Measurement of the differential $\gamma + c$-jet cross section and the ratio of differential $\gamma + c$ and $\gamma + b$ cross sections in $p\bar{p}$ collisions at $\sqrt{s} = 1.96$ TeV

D0 Collaboration
In this Letter, we present measurements of the inclusive $\gamma + c$-jet production cross sections using data collected from June 2006 to September 2011 with the D0 detector in $p\bar{p}$ collisions at $\sqrt{s} = 1.96$ TeV which correspond to an integrated luminosity of $8.7 \pm 0.5$ fb$^{-1}$ [2]. The cross section is measured differentially as a function of $p_T^\gamma$ for photons within rapidities $|y|^c < 1.0$ and $30 < p_T^c < 300$ GeV, while the $c$-quark jet is required to have $|y|^c < 1.5$ and $p_T^c > 15$ GeV. In comparison to our previous $\gamma + c$-jet measurement [3], we now retain all events having at least one jet originating from a charm quark, as opposed to considering only the events in which the charm jet candidate is the jet with highest $p_T$. To increase the signal yield and study a trend in the data/theory ratio observed in Ref. [3], we have extended the rapidity [4] region from $|y|^c < 0.8$ to $|y|^c < 1.5$ and combine regions with positive and negative products of rapidities, $y^\gamma y^c$. In addition, an increased integrated luminosity by about a factor of nine allows the $p_T^\gamma$ range to be extended to higher values.

The data set and event selections used in our measurement are similar to those used in the recently published measurement of the $\gamma + b$-jet differential cross section [5]. However, because of the difficulty in discriminating $c$-jets from light jets, this measurement adopts a different strategy for the estimation of the $c$-jet fraction. Here we apply a significantly more stringent requirement for selecting heavy-flavor jets (originating from $c$ and $b$ quarks) in order to suppress the rates of light jets (originating from light quarks or gluons) by an additional factor of 2.5–3. This small residual contribution of light jets is then subtracted from the selected data.
events prior to performing the fit with the discriminant templates of b-jets and c-jets to extract the c-jet fraction. Using this event selection criteria, we reproduce the results for the $\gamma + b$-jet cross section, measure the $\gamma + c$-jet cross section and calculate the ratio $\sigma(\gamma + c)/\sigma(\gamma + b)$ in bins of $p_T^\gamma$. Common experimental uncertainties and dependence on the higher-order corrections in theory are reduced in the ratio, allowing a precise study of the relative $\sigma(\gamma + c)/\sigma(\gamma + b)$ rates.

The D0 detector is a general purpose detector described in detail elsewhere [6]. The subdetectors most relevant to this analysis are the central tracking system, composed of a silicon microstrip tracker (SMT) and a central fiber tracker (CFT) embedded in a 1.9 T solenoidal magnetic field, the central preshower detector (CPS), and the calorimeter. The CPS is located immediately before the inner layer of the central calorimeter and is formed of approximately one radiation length of lead absorber followed by three layers of scintillating strips. The calorimeter consists of a central section (CC) with coverage in pseudorapidity of $|\eta| < 1.1$ [7], and two end calorimeters (EC) extending coverage to $|\eta| < 4.2$, all housed in separate cryostats, with scintillators between the CC and EC cryostats providing sampling of developing showers for $1.1 < |\eta| < 1.4$. The electromagnetic (EM) section of the calorimeter is segmented longitudinally into four layers (EMi, $i = 1–4$), with transverse segmentation into cells of size $\Delta R_{det} \times \Delta\phi = 0.1 \times 0.1$ [7], except EM3 (near the EM shower maximum), where it is $0.05 \times 0.05$. The calorimeter allows for a precise measurement of the energy and direction of electrons and photons, providing an energy resolution of approximately 4% (3%) at an energy of 30 (100) GeV, and an angular resolution of about 0.01 radians. The energy response of the calorimeter to photons is calibrated using electrons from Z boson decays. Since electrons and photons interact differently in the detector material before the calorimeter, additional energy corrections as a function of $p_T^\gamma$ are derived using a detailed GEANT-based [8] simulation of the D0 detector response. These corrections are largest, $\approx 2\%$, at photon energies of about 30 GeV.

The data used in this analysis are collected using a combination of triggers requiring a cluster of energy in the EM calorimeter with loose shower shape requirements. The trigger efficiency is $\approx 98\%$ for photon candidates with $p_T^\gamma \approx 30$ GeV and $\approx 100\%$ for $p_T^\gamma > 40$ GeV.

Offline event selection requires a reconstructed $p\bar{p}$ interaction vertex [9] within 60 cm of the center of the detector along the beam axis. The missing transverse momentum in the event is required to be less than $0.7 p_T^\gamma$ to suppress the background contribution from $W \rightarrow e\nu$ decays. These requirements are highly efficient ($\geq 98\%$) for signal events.

The photon selection criteria in the current measurement are identical to those used in Ref. [5]. The photon selection efficiency and acceptance are calculated using samples of $\gamma + c$-jet events, generated using the SHERPA [10] and PYTHIA [11] event generators. The samples are processed through a GEANT-based [8] simulation of the D0 detector response, followed by reconstruction using the same algorithms as applied to data. As in Ref. [5], in the efficiency and acceptance calculations the photon is required to be isolated at the particle level by $E_T^{iso} = E_T^{\gamma} \times (0.4) - E_T^{\gamma} < 2.5$ GeV, where $E_T^{iso}$ is the total transverse energy of particles within a cone of radius $R = \sqrt{(\Delta\eta)^2 + (\Delta\phi)^2} = 0.4$ centered on the photon and $E_T^{\gamma}$ is the photon transverse energy. The particle level includes all stable particles as defined in Ref. [12]. The photon acceptance varies within $(82–90\%)$ with a relative systematic uncertainty of $(2–5\%)$, while the efficiency to pass photon identification criteria is $(68–85\%)$ with $3\%$ systematic uncertainty.

At least one jet with $p_T^j > 15$ GeV and $|\eta^j| < 1.5$ must be reconstructed in each event. Jets are reconstructed using the D0 Run II algorithm [13] with a cone radius of $R = 0.5$. The jet acceptance with respect to the $p_T^{j\gamma}$ and $|\eta^{j\gamma}|$ varies between 91% and 100% in different $p_T^{j\gamma}$ bins. Uncertainties on the acceptance due to the jet energy scale, jet energy resolution, and the difference between results obtained with SHERPA and PYTHIA are in the range of $(1–4\%)$. A set of criteria is imposed to have sufficient information to classify the jet as a heavy-flavor candidate: the jet is required to have at least two associated tracks with $p_T > 0.5$ GeV with at least one hit in the SMT, and at least one of these tracks must have $p_T > 1.0$ GeV. These criteria have an efficiency of about 90%.

To enrich the sample with heavy-flavor jets, a neural net based b-tagging algorithm (b-NN) is applied. It exploits the longer lifetimes of b-flavored hadrons in comparison to their lighter counterparts, after the rejection of long-lived $K_S^\pm$ and $\Lambda$ decays [14]. The inputs to the b-NN combine information from the impact parameter of displaced tracks and the topological properties of secondary vertices reconstructed in the jet to provide a continuous output value that tends towards one for b-jets and zero for light quark jets. Events are required to contain at least one jet satisfying b-NN output $> 0.7$. This b-tagging selection suppresses light jet candidates by about $5\%$ of the heavy-flavor enhanced sample. The efficiency for b- and c-jets to satisfy the b-tagging requirements in the simulation is scaled by the data-to-Monte Carlo (MC) correction factors parametrized as a function of jet $p_T$ and $\eta$ [14]. Depending on $p_T^\gamma$, the selection efficiency for this requirement is $(8–10\%)$ for c-jets with relative systematic uncertainties of $(6–23\%)$, caused by uncertainty on the data-to-MC correction factors. The maximum difference between the efficiencies for c-jets arising from the Compton-like and annihilation subprocesses is about 10%.

The relative rate of remaining light jets (“light/all”) in the sample after the final selection is estimated using SHERPA and PYTHIA $\gamma +$ jet events, taking into account the data-to-MC correction factors as described in Ref. [14]. The light jet rates predicted by PYTHIA and SHERPA agree within $5\%$. The central predictions are taken from SHERPA, which agrees with measured $\gamma +$ jet [15] and $\gamma + b$-jet [5] cross sections within $(10–25\%)$.

After application of all selection requirements, $130\,875$ events remain. We estimate the photon purity using an artificial neural network discriminant [5]. The distribution of the output of this discriminant ($Q_{NN}$) is fitted to a linear combination of templates for photons and jets obtained from simulated $\gamma +$ jet and dijet samples, respectively. An independent fit is performed in each $p_T^\gamma$ bin. It yields photon purities between $62\%$ and $99\%$, which are close to those obtained in Ref. [5]. Their systematic uncertainties are of a comparable magnitude, $(5–9\%)$.

The invariant mass of all charged particles associated with a displaced secondary vertex in a jet, $M_{SV}$, is a powerful variable to discriminate from b-jets. Since the $M_{SV}$ templates for light and c-jets after application of tight b-tagging requirements are quite close to each other, we first subtract the remaining small fraction (1–5%) of light jets from the data. Then the c-jet fraction is determined by fitting $M_{SV}$ templates for c- and b-jets to the $\gamma +$ heavy-flavor jet) data. Jets from b quarks contain secondary vertices that have in general larger values of $M_{SV}$ as compared to c-jets and the region beyond $M_{SV} > 2.0$ GeV is strongly dominated by b-jets. The templates for b- and c-jets are obtained from PYTHIA samples of $\gamma +$ b-jet and $\gamma +$ c-jet events, respectively, and are consistent with the templates generated using SHERPA. The templates for jets arising from the Compton-like and annihilation subprocesses are also similar to each other.

The result of a maximum likelihood fit to the $M_{SV}$ templates, normalized to the number of events in data, is shown in Fig. 1 for the $50 < p_T^\gamma < 60$ GeV bin as an example. Fits in the other $p_T^\gamma$ bins are of similar quality. As shown in Fig. 2, the estimated c-jet fraction obtained from the fits in the final selected heavy-flavor
sample after subtraction of the light-jet component drops with increasing $p_T^\gamma$, on average, from about 52% to about 40%. The corresponding fit uncertainties range between (4–32)%, increasing towards higher $p_T^\gamma$, and are dominated by the limited data statistics. Since the fits are performed independently in each $p_T^\gamma$ bin, these uncertainties are uncorrelated from bin to bin. Additional systematic uncertainties are estimated by varying the relative rate of light jets by ±50% and by considering the differences in the light-jet predictions from SHERPA and PYTHIA event generators. These two sources lead to uncertainties on the c-jet fraction of about (5–9)% and 6%, respectively.

Systematic uncertainty on the measured cross sections due to the b-NN selection is estimated by performing the measurement with looser b-NN selections: requiring b-NN output > 0.3 or > 0.5 instead of 0.7. In both cases, this significantly increases the light-jet rate and also changes the c- and b-jet fractions, resulting in a variation of the $\gamma+c$-jet cross section of ≤7%. This variation is taken as a systematic uncertainty on the cross section.

The data, corrected for photon and jet acceptance, reconstruction efficiencies and the admixture of background events, are presented at the particle level [12] for comparison with predictions unfolded by the data for effects of detector resolution.

The differential cross sections of $\gamma+c$-jet production are extracted in nine bins of $p_T^\gamma$. They are listed in Table 1 and are shown in Fig. 3. The data points are plotted at the values of $p_T^\gamma$ for which the value of a smooth function describing the dependence of the cross section on $p_T^\gamma$ equals the averaged cross section in the bin [16].

The statistical uncertainty of the results ranges from 2% in the first $p_T^\gamma$ bin to 11% in the last $p_T^\gamma$ bin. The total systematic uncertainty varies between 14% and 42% across these bins. The main sources of uncertainty at low $p_T^\gamma$ are due to the photon purity (up to 8%), the c-jet fraction (10–33%), and the luminosity (6%) [2]. The total systematic uncertainties ($\delta_{\text{syst}}$) and the bin-to-bin uncorrelated components ($\delta_{\text{uncyst}}$) are shown in Table 1.

Next-to-leading order (NLO) perturbative QCD predictions of order $O(\alpha_s^2)$ [1,17], with the renormalization scale $\mu_R$, factorization scale $\mu_F$, and fragmentation scale $\mu_F$ all set to $p_T^\gamma$, are given in Table 1. The uncertainty from the scale choice is estimated through a simultaneous variation of all three scales by a factor of two, i.e., for $\mu_R, \mu_F = 0.5 p_T^\gamma$ and $2 p_T^\gamma$, and is found to be similar to those for $\gamma+b$-jet predictions (5–30%), being larger at higher $p_T^\gamma$ [5]. The NLO predictions utilize CTEQ6.6M PDFs [18] and are corrected for non-perturbative effects of parton-to-hadron fragmentation and multiple parton interactions. The latter are evaluated using SHERPA and PYTHIA MC samples generated using their default settings [10,11]. The overall corrections vary within 0.90–0.95 with

Fig. 1. (Color online.) Distribution of secondary vertex mass after all selection criteria for a representative bin of 50 < $p_T^\gamma$ < 60 GeV. The expected contribution from the light-jet component has been subtracted from the data. The distributions for the b-jet and c-jet templates (with statistical uncertainties) are shown normalized to their respective fitted fractions.

Fig. 2. The c-jet fraction in data after subtraction of light-jet background as a function of $p_T^\gamma$ derived from the template fit to the heavy quark jet data sample after applying all selections. The error bars include statistical and systematic uncertainties. Binning is the same as given in Table 1.

The differential cross sections of $\gamma+c$-jet production are extracted in nine bins of $p_T^\gamma$. They are listed in Table 1 and are shown in Fig. 3. The data points are plotted at the values of $p_T^\gamma$ for which the value of a smooth function describing the dependence of the cross section on $p_T^\gamma$ equals the averaged cross section in the bin [16].

The statistical uncertainty of the results ranges from 2% in the first $p_T^\gamma$ bin to 11% in the last $p_T^\gamma$ bin. The total systematic uncertainty varies between 14% and 42% across these bins. The main sources of uncertainty at low $p_T^\gamma$ are due to the photon purity (up to 8%), the c-jet fraction (10–33%), and the luminosity (6%) [2]. The total systematic uncertainties ($\delta_{\text{syst}}$) and the bin-to-bin uncorrelated components ($\delta_{\text{uncyst}}$) are shown in Table 1.

Next-to-leading order (NLO) perturbative QCD predictions of order $O(\alpha_s^2)$ [1,17], with the renormalization scale $\mu_R$, factorization scale $\mu_F$, and fragmentation scale $\mu_F$ all set to $p_T^\gamma$, are given in Table 1. The uncertainty from the scale choice is estimated through a simultaneous variation of all three scales by a factor of two, i.e., for $\mu_R, \mu_F = 0.5 p_T^\gamma$ and $2 p_T^\gamma$, and is found to be similar to those for $\gamma+b$-jet predictions (5–30%), being larger at higher $p_T^\gamma$ [5]. The NLO predictions utilize CTEQ6.6M PDFs [18] and are corrected for non-perturbative effects of parton-to-hadron fragmentation and multiple parton interactions. The latter are evaluated using SHERPA and PYTHIA MC samples generated using their default settings [10,11]. The overall corrections vary within 0.90–0.95 with
an uncertainty of $\lesssim 2\%$ assigned to account for the difference between the two MC generators.

The predictions based on the $k_T$-factorization approach [19,20] and unintegrated parton distributions [21] are also given in Table 1. The resummation of gluon diagrams with gluon transverse momentum ($k_T$) above a scale $\mu$ of order 1 GeV, leads to a broadening of the photon transverse momentum distribution in this approach [19]. The scale uncertainties on these predictions vary from about $-28\% / +31\%$ at $30 < p_T^\gamma < 40$ GeV to about $+14\% / +5\%$ in the last $p_T^\gamma$ bin.

Table 1 also contains predictions from thesherpa [10] event generator with thecteq6.1L PDF set. It includes only 2 $\rightarrow 2$ matrix elements (ME) with gc $\rightarrow$ γc and qg $\rightarrow$ γg scatterings (defined at LO) followed by g $\rightarrow$ cc splitting in the parton shower (PS). We also provide predictions by thesherpa MC event generator [10] with thecteq6.6M PDF set [18]. Matching between the ME partons and the PS jets follows the prescription given in Ref. [15], with the matching scale taken to be 15 GeV. Systematic uncertainties are estimated by varying the ME–PS matching scale by $\pm 5$ GeV around the chosen central value [22], resulting in a $\pm 7\%$ cross-section variation.

All theoretical predictions are obtained using the photon isolation requirement of $E_{\text{iso}}^\gamma < 2.5$ GeV. The predictions are compared to data in Fig. 3 as a function of $p_T^\gamma$. The ratios of data over the NLO QCD calculations and of the various theoretical predictions to the NLO QCD calculations are presented in Fig. 4. The NLO predictions with ctqeg6.6M agree with MSTW2008 [23] and ABKM09NLO [24] within 10%. Parameterizations for models containing intrinsic charm (IC) have been included in ctqeg6.6c [25]. Here we consider the BHPS IC model [26,27], based on the Fock space picture of the nucleon structure [28], in which intrinsic charm appears mainly at large momentum fractions $x$, and the sea-like model in which the charm PDF is sea-like, similar to that of the light-flavor sea quarks. The NLO QCD predictions based on these intrinsic charm models are normalized to the standard ctqeg predictions and are also shown in Fig. 4. Both non-perturbative intrinsic charm models predict a higher $\gamma + c$-jet cross section in the case of the BHPS model, the ratio grows with $p_T^\gamma$, while an opposite trend is exhibited by the sea-like model.

The measured cross sections are in agreement with the NLO QCD predictions within theoretical and experimental uncertainties in the region of $30 < p_T^\gamma < 70$ GeV, but show systematic disagreement for larger $p_T^\gamma$. The cross section slope in data differs significantly from the NLO QCD prediction. The results suggest a need for higher-order perturbative QCD corrections in the large $p_T^\gamma$ region, which is dominated by the annihilation process $qq' \rightarrow γγ$ (with $g \rightarrow cc$), and resummation of diagrams with additional gluon radiation. In addition, the underestimation of the rates for diagrams with $g \rightarrow cc$ splittings may result in lower theoretical predictions of cross sections as suggested by LEP [29], LHCB [30] and ATLAS [31] results. The prediction from the $k_T$-factorization approach is in better agreement with data at $p_T^\gamma > 120$ GeV. However, it underestimates the cross section in the low and intermediate $p_T^\gamma$ region. The $γ + c$-jet cross section as predicted bysherpa becomes higher than the NLO QCD prediction at large $p_T^\gamma$, but is still lower than the measured values. It has been suggested that combining NLO parton-level calculations for the ME with PS predictions [32] will improve the description of the data [33].

In addition to measuring the $γ + c$-jet cross section, we also obtain results for the $γ + b$-jet cross section using the new tight $b$-NN selection. The values of the obtained $γ + b$-jet cross section agree within 10% (i.e. within uncertainties) with the published results [5] obtained with a looser $b$-NN selection. We use them to calculate the ratio $\rho(γ + c) / ρ(γ + b)$ in bins of $p_T^\gamma$. In this ratio, many experimental systematic uncertainties cancel. Also, theory predictions of the ratio are less sensitive to the scale uncertainties, and effects from missing higher-order terms that impact the normalizations of the cross sections. The remaining uncertainties are caused by largely (65–67%) correlated uncertainties coming from the fitting of $c$-jet and $b$-jet MSTW templates to data, and by other uncertainties on the $c$-jet fractions discussed above. The systematic uncertainties on the ratio vary within (6–26%), being largest at high $p_T^\gamma$. Theoretical scale uncertainties, estimated by varying scales by a factor of two (to $μ_{R,F} = 0.5p_T^\gamma$ and $2p_T^\gamma$) in the same way for
The $\sigma(\gamma + c)/\sigma(\gamma + b)$ cross section ratio in bins of $p_T^\gamma$ for $|y^\gamma| < 1.0$, $p_T^{\gamma\gamma} > 15$ GeV and $|y^{\gamma\gamma}| < 1.5$ together with statistical uncertainties ($\delta_{\text{stat}}$), total systematic uncertainties ($\delta_{\text{syst}}$), and the uncorrelated component of $\delta_{\text{syst}}$ ($\delta_{\text{syst}}^{\text{unc}}$). The column $\delta_{\text{tot}}$ shows total experimental uncertainty obtained by adding $\delta_{\text{stat}}$ and $\delta_{\text{syst}}$ in quadrature. The last four columns show theoretical predictions obtained using NLO QCD, $k_T$-factorization, PYTHIA and SHERPA event generators.

Fig. 5. (Color online.) The ratio of $\gamma + c$-jet and $\gamma + b$-jet production cross sections for data together with theoretical predictions as a function of $p_T^\gamma$. The uncertainties on the data include both statistical (inner error bar) and total uncertainties (full error bar). Predictions given by $k_T$-factorization [19,20], SHERPA [10] and PYTHIA [11] are also shown. The PYTHIA predictions with a contribution from the annihilation $c\bar{c}$-jet production as a function of $p_T^\gamma$, at the Fermilab Tevatron $p\bar{p}$ collider. Our results cover the kinematic range $30 < p_T^\gamma < 300$ GeV, $|y^\gamma| < 1.0$, and $|y^{\gamma\gamma}| < 1.5$. In the same kinematic region, and in the same $p_T^\gamma$ bins, we have measured the $\sigma(\gamma + c)/\sigma(\gamma + b)$ cross section ratio. None of the theoretical predictions considered give good description of the data in all $p_T^\gamma$ bins. Such a description might be achieved by including higher-order corrections into the QCD predictions, while at $p_T^\gamma \geq 80$ GeV the observed difference from data may also be caused by an underestimated contribution from gluon splitting $g \to c\bar{c}$ [29–31] in the annihilation process or by contribution from intrinsic charm. The presented results can be used for further development of theoretical models to understand production of high energy photons in association with heavy-flavor jets.

Acknowledgements

We are grateful to the authors of the theoretical calculations, T. Stavreva, J. Owens, N. Zотов, and F. Siegenthaler for providing dedicated predictions and for many useful discussions.

We thank the staffs at Fermilab and collaborating institutions, and acknowledge support from the DOE and NSF (USA); CEA and CNRS/IN2P3 (France); MON, NRC KI and RFBR (Russia); CNPq, FAPESP, FAP-CTES and FUNDUNESP (Brazil); DAF, DST (India); Colciencias (Colombia); CONACYT (Mexico); NRF (Republic of Korea); FOM (The Netherlands); STFC and the Royal Society (United Kingdom); MSMT and GACR (Czech Republic); BMBF and DFG (Germany); SFI (Ireland); The Swedish Research Council (Sweden); and CAS and CNSF (China).

References

[4] The rapidity $y$ is related to the polar scattering angle $\theta$ with respect to the proton beam axis by $y = 0.5 \ln \left(1 + \beta \cos \theta / (1 - \beta \cos \theta)\right)$, where $\beta$ is defined as the ratio between momentum and energy $\beta = |p|/E$.
The polar angle $\theta$ and the azimuthal angle $\phi$ are defined with respect to the positive z axis, which is along the proton beam direction. Pseudorapidity is defined as $\eta = -\ln(\tan(\theta/2))$. Also, $\eta_{\text{det}}$ is the pseudorapidity measured with respect to the center of the detector.

The primary $p\bar{p}$ interaction vertex is the most likely hard collision point, among possibly several collisions within a specific beam crossing. The algorithm for defining primary vertex can be found in [14].

We choose the following ME–PS matching parameters: the energy scale $Q_0 = 15$ GeV and parameter $D = 0.4$, where $D$ is taken to be of the size of the photon isolation cone.
