Prevalence of interpersonal trauma exposure and trauma-related disorders in severe mental illness

Maria W. Mauritz1,2*, Peter J. J. Goossens2,3,4, Nel Draijer5 and Theo van Achterberg2

1Community Mental Health Care Unit/Long Treatment, GGNet, Warnsveld, The Netherlands; 2Scientific Institute for Quality of Healthcare, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands; 3Saxon University of Applied Sciences, Expertise Centre of Health, Social Work & Technology, Deventer, The Netherlands; 4Specialist Centre for Bipolar Disorders, Dimece, Deventer, The Netherlands; 5Department of Psychiatry, VU University Medical Center, Amsterdam, The Netherlands

Background: Interpersonal trauma exposure and trauma-related disorders in people with severe mental illness (SMI) are often not recognized in clinical practice.

Objective: To substantiate the prevalence of interpersonal trauma exposure and trauma-related disorders in people with SMI.

Methods: We conducted a systematic review of four databases (1980–2010) and then described and analysed 33 studies in terms of primary diagnosis and instruments used to measure trauma exposure and trauma-related disorders.

Results: Population-weighted mean prevalence rates in SMI were physical abuse 47% (range 25–72%), sexual abuse 37% (range 24–49%), and posttraumatic stress disorder (PTSD) 30% (range 20–47%). Compared to men, women showed a higher prevalence of sexual abuse in schizophrenia spectrum disorder, bipolar disorder, and mixed diagnosis groups labelled as having SMI.

Conclusions: Prevalence rates of interpersonal trauma and trauma-related disorders were significantly higher in SMI than in the general population. Emotional abuse and neglect, physical neglect, complex PTSD, and dissociative disorders have been scarcely examined in SMI.

Keywords: Childhood trauma; sexual abuse; physical abuse; emotional abuse; neglect; posttraumatic stress disorder; complex posttraumatic stress disorder; dissociative disorder; severe mental illness

Trauma exposure and posttraumatic stress disorder (PTSD) have been receiving growing attention in research over the last decades. Despite this, trauma exposure and PTSD are significantly overlooked in the treatment of patients with severe mental illness (SMI): documentation of trauma and symptoms of trauma is exceptionally low in the medical records of patients with SMI. Improved recognition is thus needed to provide adequate treatment and meaningful services for this vulnerable population (Cusack, Grubaugh, Knapp, & Frueh, 2006; Mueser et al., 2004; van den Berg & van der Gaag, 2012). One reason for the poor recognition of trauma in patients with SMI is the overlap which often occurs between the symptoms of trauma-related disorders and the symptoms of SMI. For instance, dissociation and psychotic symptoms can be signs of both PTSD and schizophrenia (Kilcommons & Morrison, 2005; Lysaker & LaRocco, 2008; van Gerven, Hart, Nijenhuis, & Kuipers, 2002). Another reason for poor recognition of trauma in patients with SMI is that many clinicians have been hesitant to pay attention to traumatic experiences in the past because they think that this could lead to further distress and impairment. There is, however, no evidence for this conviction (Cusack et al., 2006; Griffin, Resick, Waldrop, & Mechanic, 2003). Finally, the majority of patients with SMI entered the mental health care system a long time ago when knowledge of the role of traumatic experiences in the onset and course of these disorders was limited. Among the traumatic experiences, repeated
interpersonal trauma, such as emotional, physical, and sexual abuse, can lead to both PTSD as well as more severe trauma-related disorders like complex PTSD and dissociative disorders. It has further been documented that a history of interpersonal trauma exposure and the existence of trauma-related disorders negatively affects the course of SMI (Friedl & Draijer, 2000; Mueser, Rosenberg, Goodman, & Trumbetta, 2002; Mueser et al., 2004). Despite this, the prevalence of interpersonal trauma exposure and trauma-related disorders in people with SMI has been scarcely investigated.

In order to gain insight into interpersonal trauma exposure and trauma-related disorders among patients with SMI, we conducted a systematic review of the relevant research literature with the following research question in mind.

What is the prevalence of interpersonal trauma exposure and trauma-related disorders in patients with severe mental illness (SMI) receiving mental health care?

As SMI and trauma-related disorders are the central concepts in this review, their definitions—which are still developing—will first be considered below.

**Severe mental illness**

The concept of SMI often lacks clarity and specificity. “SMI” is the abbreviation commonly used for the following: severe mental illness, serious mental illness, or severe and persistent mental illness. When Schinnar, Rothbard, and Kanter (1990) compared 17 definitions of SMI used in the USA between 1972 and 1987, they decided that the optimal definition was the one provided by the National Institute of Mental Health (NIMH) with the following criteria: a diagnosis of non-organic psychosis or personality disorder; duration in terms of prolonged illness and long-term treatment; and disability including three of eight criteria: (a) social behaviour demanding a mental health intervention; (b) limited ability to obtain assistance; (c) impaired activities of daily living and basic needs; (d) impaired social functioning; (e) impaired performance in employment or (f) non-work (homemaking); (g) vulnerability to stress; and (h) disability that causes dependency (National Institute of Mental Health [NIMH], 1987; Schinnar et al., 1990).

Kessler et al. (2003) defined SMI as any 12-month DSM-IV disorder, other than a substance use disorder, with a global assessment of functioning (GAF) score <60. In Europe, Ruggeri, Leese, Thornicroft, Bisoffi, and Tansella (2000) have operationalized the NIMH criteria for SMI along two dimensions: duration of treatment (≥2 years) and degree of dysfunction (GAF-score ≤50 or 70 depending on the primary diagnosis) for any mental disorder.

**Posttraumatic stress disorder**

In the DSM-IV-TR, posttraumatic stress disorder (PTSD) is classified as an anxiety disorder which follows a traumatic event and entails intense fear and/or feelings of helplessness. Symptoms are divided into three clusters: (a) intrusions in the form of re-experiencing the trauma via nightmares, obsessive thoughts and/or flashbacks; (b) avoidance of situations, people and/or objects which remind the patient of the traumatic event; and (c) increased anxiety in general, possibly with a heightened startle response and alertness (APA, 2000).

**Complex PTSD**

PTSD captures only a limited aspect of posttraumatic psychopathology, especially in victims with severe and prolonged trauma. Herman (1992) has identified seven symptom clusters for these victim groups: dysregulation of (a) affect and impulses; (b) attention or consciousness; (c) self-perceptions; (d) perceptions of the perpetrator; (e) relations with others; (f) somatization; and (g) systems of meaning. This constellation of symptom clusters is referred to as complex PTSD or disorder of extreme stress not otherwise specified (DESNOS) but classified in the DSM-IV as PTSD with associated features (APA, 2000; Herman, 1992; Pelcovitz et al., 1997; van der Kolk, Roth, Pelcovitz, Sunday, & Spinazzola, 2005).

Bryant (2010) has argued that emotion dysregulation is the core feature of complex PTSD. Dysregulated affect and impulses, self-perceptions and relations with others are also highly characteristic of personality disorders, particularly borderline personality disorder (BPD) (APA, 2000; Herman, Perry, & van der Kolk, 1989). This makes BPD difficult to distinguish from complex PTSD. Lewis and Grenyer (2009) reviewed the on-going controversy on the nature of the relationship between complex PTSD and BPD concluded that these disorders often cohere, but are separate phenomena.

**Dissociation and dissociative disorders**

It has been further argued in the literature that dissociation is a core feature of complex PTSD. Van der Hart, Nijenhuis, and Steele (2005) have postulated that traumatization essentially involves some degree of division or dissociation of the psychobiological systems which constitute identity. Dissociative identity disorder (DID) and dissociative disorder not otherwise specified (DDNOS) have indeed been found to be highly correlated with a history of severe and prolonged traumatic experiences (82%) and therefore were considered as trauma-related disorders in such cases (Boon & Draijer, 1993; Draijer & Boon, 1990; Sar, 2011).

Based on this overview of concepts, we used the following definitions in our review: SMI was defined as any mental disorder, other than a substance use disorder,
with the following two dimensions: duration of mental illness and obvious dysfunction. PTSD, complex PTSD, DID, and DDNOS were considered as trauma-related disorders. BPD was considered as a separate disorder.

Methods

Operationalization of concepts

In this review, the two dimensions of SMI were operationalized as (1) duration of mental illness \( \geq 2 \) years (Ruggeri et al., 2000) and (2) obvious dysfunction as a GAF-score \( \leq 60 \) or a clear description of a minimum of three disabilities according to the NIMH criteria for SMI (Kessler et al., 2003; NIMH, 1987). Interpersonal trauma was defined as involving any of the following traumatic experiences: emotional abuse (EA), emotional neglect (EN), physical abuse (PA), physical neglect (PN), and/or sexual abuse (SA) in childhood and/or adulthood. Trauma-related disorders were considered present when a diagnosis had been made of PTSD, PTSD with associated features, complex PTSD, DESNOS, DID, and/or DDNOS.

Search

The Medline, PsycINFO, Embase, and CINAHL databases were searched for the period between 1980 and 2010. The subject headings and keywords were as follows. For SMI, schizophrenia/psychotic disorders, bipolar disorders, major (chronic) depression/major depressive disorders, anxiety disorders, eating disorders, and personality disorders. For interpersonal trauma exposure: child abuse, emotional abuse; emotional neglect; physical abuse; physical neglect; sexual abuse; physical assault; and sexual assault. For trauma-related disorders: PTSD, complex PTSD, DESNOS, and dissociative disorders. Prevalence was searched using the following terms: prevalence, co-morbidity, and risk factors.

All of the keywords for trauma and prevalence were first combined. These words were then combined with each mental disorder. The exact search strategy is outlined in Supplement 1.

Selection criteria

Inclusion criteria for peer-reviewed publications using adult study populations (\( \geq 18 \) years) were as follows:

1. SMI was labelled as such or one of the following mental disorders was mentioned: schizophrenia spectrum disorders, bipolar disorders, major depressive disorders, anxiety disorders, eating disorders, or personality disorders
   a. Classified in DSM-III, DSM-IV or DSM-IV-tr

   b. SMI determined on the basis of both dimensions:
      i. Duration of illness and/or treatment (\( \geq 2 \) years)
      ii. Obvious dysfunction (GAF \( \leq 60 \) or clear description of minimum of three impairments according the NIMH definition) and

   2. Report of prevalence of interpersonal trauma exposure with specific description:
      a. Type of abuse, reference period (childhood, adulthood, lifetime)
      b. Description of the diagnostic instruments used and

   3. Report of prevalence of trauma-related disorders:
      a. PTSD, complex PTSD (PTSD with associated features or DESNOS), DID, and/or DDNOS
      b. Relevant diagnostic instruments were described

The exclusion criteria for our review were as follows:

1. Substance use disorders as only diagnosis
2. Developmental disorders; delirium, dementia, amnesia or other cognitive disorders with a physical origin
3. Forensic and/or imprisoned populations

Selection

Figure 1 shows the selection of the publications for this review. Of the initial 6,299 unique hits, 4,422 publications were excluded because the title did not mention SMI and/or interpersonal trauma or trauma-related disorders, or the title mentioned the age \( < 18 \). The abstracts from the remaining 1,877 publications were independently reviewed by two researchers. Of these, 104 described the prevalence of interpersonal trauma exposure or trauma-related disorders in SMI and the entire publication was therefore reviewed by three researchers independently. In the end, 33 publications described the prevalence of both trauma exposure and trauma-related disorders in SMI and were thus selected for inclusion in the review.

Those studies in which SMI was explicitly mentioned only included the following disorders: schizophrenia (spectrum disorder), bipolar disorder, major depressive disorder, and personality disorder. Anxiety disorders and eating disorders were never characterized as SMI in the selected publications and contained insufficient information about the duration of illness and obvious dysfunction. For this reason, anxiety or eating disorder as the primary diagnosis were excluded from our review although the prevalence of trauma in such disorders is notable (Brewerton, 2007; Grant, Beck, Marques, Palyo, & Clapp, 2008; Stein et al., 1996). One study of bipolar
disorders was also excluded from our review due to the exclusion of the severely ill subgroup of patients (Brown, McBride, Bauer, & Williford, 2005).

Data extraction
The following data were extracted from the 33 publications included in the review:

(1) Population characteristics: gender, age, country, care setting, research type
(2) Primary diagnosis for SMI
(3) Diagnostic instruments used
(4) Prevalence rates for interpersonal trauma: type (EA, EN, PA, PN, SA), reference period (childhood, adulthood, lifetime)
(5) Prevalence rates for trauma-related disorder: description of diagnosis
(6) General conclusions of the study

Quality assessment
The following quality aspects of the studies included in the review were assessed:

(1) Study design
(2) Sampling: inclusion and exclusion criteria; (non)response
(3) Use of diagnostic instruments to determine primary diagnosis (SMI)
(4) Use of diagnostic and research instruments to measure trauma exposure and trauma-related disorders

Analysis
Prevalence rates were determined according to diagnostic group and gender. To facilitate comparison of the prevalence rates, population-weighted means were calculated for each of the diagnostic groups. This was also done for gender when reported. A formal meta-analysis was not performed because of the wide variety of objectives and research designs in the studies, the heterogeneity of the instruments used to assess interpersonal trauma exposure and the affected stage of life, e.g., childhood, adulthood, or lifetime.
Results
In the 33 studies included in our review, the following disorders were addressed: bipolar disorder (8), major depressive disorder (6), schizophrenia spectrum disorder (7), personality disorder (5), and mixed diagnostic groups, explicitly labelled as SMI (7). All publications described the prevalence of interpersonal trauma exposure, and all but one (Ross & Keyes, 2004) described the prevalence of PTSD. One publication described the prevalence of complex PTSD (Barnow, Plock, Spitzer, Hamann, & Freyberger, 2005) and two reported the prevalence of DID and/or DDNOS (Ross & Keyes, 2004; Sar et al., 2003). The characteristics of the studies are outlined in Table 1.

Quality of the included studies
All 33 publications fulfilled the required inclusion criteria for primary diagnosis and age. Eight publications described additional selection criteria and also mentioned training of the diagnostic interviewers (Table 1). The other publications described only additional selection criteria or the training of the interviewers but not both. The instruments used for the primary diagnosis in the 33 studies are reported in Table 1 and described further in Supplement 2. The diagnostic instruments used to assess trauma exposure and trauma-related disorders are similarly reported in Table 1 and described further in Supplement 3.

Prevalence of PA, SA, and PTSD according to diagnostic group and reference period
Prevalence rates of PA and SA were examined in all 33 studies according to reference period (i.e., childhood only, adulthood only, both childhood and adulthood, or lifetime) (Fig. 2). Two studies considered PA and SA together and could not be shown in the figures. These combined lifetime prevalence rates were 40 and 53%, respectively (Neria, Bromet, Carlson, & Naz, 2005; Neria et al., 2008).

In those studies reporting on both the adult and childhood prevalence of PA, adult PA tended to be higher than childhood PA for schizophrenia spectrum disorders, personality disorders and SMI (mixed diagnoses group). Similarly, the adult prevalence of SA tended to be higher than the childhood prevalence for SMI and personality disorders (Fig. 2).

Differences in prevalence of PA, SA and PTSD across diagnostic groups
Figure 3 shows the mean prevalence rates for PA, SA, and PTSD weighted according to population size. When more than one rate was given for a particular type of trauma exposure (e.g., both childhood and adulthood), the highest prevalence rate was adopted. Prevalence rates for PA and PTSD were relatively low in bipolar and major depressive disorder. The mean prevalence of PA was most high in schizophrenia and SMI while the mean prevalence of SA and PTSD was most high in BPD and SMI.

Prevalence of PA, SA and PTSD according to diagnostic group and gender
The prevalence of PA and SA according to gender was examined in 11 studies and involved the following diagnostic groups: bipolar disorder, schizophrenia spectrum disorder, and SMI. Three of these studies also described prevalence according to gender for PTSD (Fig. 4). Prevalence rates for SA were significantly higher for women than for men, but less so for PA.

Prevalence of EA, EN, and PN according to diagnostic group and reference period
Estimates of the prevalence of EA in bipolar disorder were provided in only two studies: 43% for childhood (Maguire, Mc Cusker, Meenagh, Mulholland, & Shannon, 2008) and 6% for lifetime (Kauer-Sant’Anna et al., 2007). This large difference could reflect differences in the diagnostic instruments used in these studies (see Table 1). The childhood prevalence of EA in major depressive disorder was reported to be 39% by Gaudiano and Zimmerman (2010) and 49% by Bernet and Stein (1999). The prevalence of childhood EA was highest in the psychotic subgroup of major depression with 53% (Gaudiano & Zimmerman, 2010). In a single study of schizophrenia, the childhood prevalences of EA, EN, and PN were found to be 13, 13, and 6%, respectively (Beattie, Shannon, Kavanagh, & Mulholland, 2009).

In BPD, the prevalence of childhood EA was 60–63% (Sar et al., 2003; Zlotnick et al., 2003). The prevalence of total neglect in BPD was 60–88% (Sar et al., 2003; van den Bosch, Verheul, Langeland, & van den Brink, 2003; Zlotnick et al., 2003).

Complex PTSD and dissociative disorders
Complex PTSD in schizophrenia was investigated and present in one study, but the prevalence rate was not reported (Ford & Fournier, 2007). The current prevalence of complex PTSD in BPD was 31% (Barnow et al., 2005).

The prevalence of DID in schizophrenia has been reported to be 16% (Ross & Keyes, 2004). And the current prevalence of DID in BPD has been reported to be 24% and that of DDNOS in BPD to be 36% (Sar et al., 2003). In this study, DID only appeared in patients with both BPD and a history of trauma exposure and it also correlated with the highest prevalence of childhood trauma.

SC: Selection criteria other than inclusion criteria.
TI: Trained interviewers.
Fig. 2. Prevalence rates for physical abuse, sexual abuse, and PTSD by disorder and reference period. BD, bipolar disorder; MDD, major depressive disorder; SSD, schizophrenia spectrum disorder; SMI, severe mental illness; B, borderline; ST, schizotypal; AV, avoidant; OC, obsessive compulsive (personality disorder).
Notable clinical findings

Co-morbidity
Information on co-morbid conditions was reported in 20 publications. Of these, 13 compared co-morbidity for traumatized versus not traumatized subgroups and found a higher degree of co-morbidity for Axis I and/or Axis II disorders for all of the traumatized subgroups. The prevalence of co-morbid substance use disorders was also significantly higher for the traumatized subgroups and negatively influenced the course of mental illness (Barnow et al., 2005; Bernet & Stein, 1999; Calhoun et al., 2007; Carlier, Voerman, & Gersons, 2000; Ford & Fournier, 2007; Goldberg & Garno, 2005; Leverich et al., 2002a; Leverich, Perez, Luckenbaugh, & Post, 2002b; Lu et al., 2008; Meade et al., 2009; Oquendo et al., 2005; Rosenberg, Lu, Mueser, Jankowski, & Cournos, 2007; Ross & Keyes, 2004; Zlotnick, Mattia, & Zimmerman, 2000).

Influence of interpersonal trauma exposure and trauma-related disorders on the course of mental illness and severity of symptoms
Childhood SA and childhood EA were associated with an 8-9 year earlier onset of illness in major depressive disorder (Bernet & Stein, 1999; Zlotnick et al., 2000). Childhood PA and childhood SA were strongly associated with PTSD in psychotic subtypes of major depressive disorder (Gaudiano & Zimmerman, 2010; Zimmerman & Mattia, 1999). Childhood trauma exposure had a negative effect on the course of illness in schizophrenia spectrum disorder (Rosenberg et al., 2007). Severity of trauma exposure was associated with positive symptoms in schizophrenia (Resnick, Bond, & Mueser, 2003; Ross & Keyes, 2004; Kilcommons & Morrison, 2005). SMI patients with a history of both PA and SA attempted suicide five times more frequently (Ford & Fournier, 2007). The number of types of trauma exposure also predicted PTSD in SMI (Mueser et al., 1998).

Co-morbid lifetime PTSD predicted a worse clinical outcome for bipolar disorder: a 6-year earlier start of the symptoms, more severe symptoms, more suicide attempts and ultra-rapid cycling of mood swings (Assion et al., 2009; Kauer-Sant’Anna, 2007; Leverich et al., 2002a, b; Meade et al., 2009). PTSD was associated with more severe symptoms and more suicide attempts for major depressive disorder (Oquendo et al., 2005); it was also four times more present for the psychotic subtypes of major depressive disorder than for the non-psychotic subtypes (Gaudiano & Zimmerman, 2010; Zimmerman & Mattia, 1999). PTSD related significantly to Axis I co-morbidity and severe emotion dysregulation in BPD (Zlotnick et al., 2003). Complex PTSD, DID, and DDNOS related significantly to a chronic course of illness, severe clinical
conditions, more self-destructive behaviour and suicide attempts in BPD (Barnow et al., 2005; Sar et al., 2003).

**Discussion**

**Main findings**

The mean prevalence rates in SMI ranged according to the diagnostic group were as follows: PA 47% (range 25–72%), SA 37% (range 24–49%), and PTSD 30% (range 20–47%). Compared to men, women showed a higher prevalence of SA in schizophrenia spectrum disorder, bipolar disorder, and mixed diagnosis groups labelled as having SMI.

The prevalence rates in SMI were significantly higher than those in the general population. More specifically, the prevalence in SMI as compared to the general population was 47% versus 21% for PA and 37% versus 23% for SA. Gender differences in the prevalence of SA in SMI (20–34% for men, 44–64% for women) were roughly comparable to that in the general population (14% for men, 32% for women) (Briere & Elliott, 2003). The PTSD prevalence of 30% in SMI was also significantly higher than the PTSD prevalence of 7% among a general population of adult Americans (Kessler, Berglund, Demler, Jin, & Walters, 2005a; Kessler, Chiu, Demler, Merikangas, & Walters, 2005b).

A 35% prevalence of complex PTSD in BPD was reported in one study and distinguished from a 61% prevalence of PTSD (Barnow et al., 2005). The prevalence of complex PTSD (DESNOS) in the general population has been scarcely examined, so further comparison was not possible. One study nevertheless reported a prevalence of 1.0% (Ford, Stockton, Kaltman, & Green, 2006). The prevalence of DID was reported to be 16% in schizophrenia (Ross & Keyes, 2004) and 24% in BPD; for DDNOS, this rate was reported to be 36% in BPD (Sar et al., 2003). The prevalence of DID in the general population has been found to vary from 0.4 to 3.1%, depending on the assessment instrument used (Friedl & Draijer, 2000; Sar, 2011).

**Validity**

Our literature search covered a period of 30 years and was conducted independently on four databases. The publications included in the review were selected
by three independent reviewers. The primary diagnoses for the patients in the studies we reviewed were usually confirmed via structured interviews like the SCID-I, SCID-II, or MINI (see Supplement 2). In three of the 33 studies, only 19% of the chart diagnoses were confirmed using the SCID-I; in six of the studies, only the chart diagnosis were used. The severity of symptoms was screened for in 12 of the studies—mostly for bipolar disorder (HAM-D, YMRS), major depressive disorder (HAM-D, BDI), and sometimes schizophrenia spectrum disorder (PANSS) (see Table 1).

Trauma history was assessed in the 33 studies we reviewed using 19 different instruments. Sufficient information was generally provided by the different instruments although they differed with regard to the questions used to assess life stage and type of interpersonal trauma. As a result, the prevalence rates were difficult to compare across studies, and the population-weighted prevalence rates should be interpreted with caution.

The quality of the information provided about sampling and severity of illness differed across the studies. In the mixed diagnoses groups characterized as SMI schizophrenia spectrum disorders and/or other psychotic disorders were highly represented (approximately 60%). Almost certainly, these mixed diagnoses groups consisted of the most impaired patients showing high co-morbidity, a worse course of illness, and the highest prevalence of trauma exposure and PTSD.

Possible limitations
The aim of our literature search could not easily be related to a limited set of search terms. The search strategy we used was exhaustive but may nevertheless not have captured all relevant studies. Nearly all studies were carried out in the USA or Western Europe, with the exception of one in Brazil (Kauer-Sant’ Anna, 2007). Inclusion of only Dutch, English, French, and German language publications may have led to a loss of information.

The aim of our review was to identify the prevalence of interpersonal trauma exposure and trauma-related disorders in SMI. Thus, exclusion of publications which attended to only interpersonal trauma exposure or only trauma-related disorders may also have led to a loss of relevant information. Some publications only reported regression coefficients but not the original prevalence rates and could not be included.

Trauma, psychosis, and dissociation
PA and SA in childhood and adulthood were markedly high in psychotic disorders (PA 59%, range 32–87%; SA 33%, range 23–38%). In the SMI group, PA was 71% (range 33–86%) and SA was 49% (range 23–70%). In the psychotic subgroups of major depressive disorder, childhood PA was high (53–60%) and childhood SA was even higher (59–60%) (Gaudiano & Zimmerman, 2010; Zimmerman & Mattia, 1999). Jansen et al. (2004) also found that early childhood trauma such as PA and SA increased the risk of developing positive psychotic symptoms in adulthood in a dose-response manner. The prevalence of PTSD was 34–48% in psychotic disorders and 58–65% in psychotic subgroups of major depressive disorder.

The relationship between trauma and psychosis is nevertheless not straightforward. Trauma can certainly cause psychosis, but psychosis can conversely cause PTSD and both psychosis and PTSD can be part of a spectrum of responses to a traumatic event (Morrison, Frame, & Larkin, 2003; Seedat, Stein, Oosthuizen, Emsley, & Stein, 2003).

Two of the 33 studies included in our review attended to psychosis as an internal threat and causal factor in the occurrence of PTSD. “Internal threat” is not considered an A1-criterion for PTSD in the DSM-IV, but Lommen and Restifo (2009) have reported a prevalence rate of 39% including internal threat and 18% excluding internal threat for PTSD. Resnick et al. (2003) have similarly reported a prevalence rate of only 13% excluding internal threat. The remaining four studies attending to psychosis and schizophrenia did not report on the A1-criterion for PTSD and the extent to which internal threat related to PTSD in these studies was therefore unclear.

Psychosis and dissociation are hard to distinguish in clinical practice (Kilcommons & Morrison, 2005; Lysaker & LaRocco, 2008; van Gerven et al., 2002). When Ross and Keyes (2004) examined dissociation in schizophrenia, those patients showing dissociation were found to have more severe trauma histories, more co-morbidity, and higher scores for both positive and negative symptoms of schizophrenia when compared to patients without dissociation. Read, van Os, Morrison, and Ross (2005) have further stated in their review of childhood trauma, psychosis, and schizophrenia that hallucinations are strongly related to abuse in childhood and more or less memories of the traumatic events. Conceptualization of hallucinations as dissociative memories of traumatic events may thus be valuable for understanding the relations between trauma, psychosis and dissociation. And viewed from this perspective, “Schneiderian and other positive psychotic symptoms follow logically from the existence of a structurally dissociated psyche”. McCarthy-Jones and Davidson (2012) have also recently described the lack of love experienced by abused people. Traumatic experiences may lead to auditory hallucinations with critical voices related to frightening experiences and supportive voices related to lack of love and support.

Psychotic symptoms may thus cohere or fall in with dissociative symptoms and possibly be the result of the same underlying mechanism. Within this context,
However, Moskowitz (2011) points to conflicting paradigms: the trauma-dissociation paradigm which is focused on life events versus the neo-Kraepelinian paradigm which is genetically and biologically based. Moskowitz (2011) suggests that the integration of the paradigms into a broader bio-psycho-social paradigm could be more useful for both future research and treatment.

**Implications of our findings**

In clinical practice, assessing interpersonal trauma exposure and trauma-related disorders in SMI can reduce current underreporting and lack of treatment. Trauma history can be assessed without further impairment of the patient (Cusack et al., 2006; Griffin et al., 2003; Tucker, 2002). Patient reports of trauma have also been shown to be reliable (Goodman et al., 1999; Mueser et al., 2004).

PTSD in SMI can be treated effectively using cognitive behavioural therapy: cognitive restructuring (Marcello, Hilton-Lerro, & Mueser, 2009; Mueser et al., 2008; Lu et al., 2009), EMDR (van den Berg & van der Gaag, 2012), and prolonged exposure (van Minnen, Harned, Zoellner, & Mills, 2012). For the treatment of complex PTSD, starting with stabilizing interventions prior to EMDR or prolonged exposure has been shown to improve the overall treatment effect (Cloitre et al., 2010; Dorrepaal et al., 2010, 2012). Assessment and treatment of dissociative disorders in traumatized groups is called for in light of the severe clinical condition of such patients and their low treatment success when dissociative disorders are not recognized (Boon & Draijer, 1993; Friedl & Draijer, 2000; Hart et al., 2005; Moskowitz, 2011; Read et al., 2005; Ross & Keyes, 2004; Sar et al., 2003).

In future research, greater attention should be paid to PN, EN, and EA because these factors have been found to increase the risk of developing PTSD (Beattie et al., 2009; Bernet & Stein, 1999; Gaudiano & Zimmerman, 2010; Maguire et al., 2008; Sar et al., 2003). Complex PTSD and DID should be given greater attention in light of their negative influence on the course of a patient’s mental illness and quality of life (Barnow et al., 2005; Read et al., 2005; Ross & Keyes, 2004; Sar et al., 2003).

**Conclusion**

The prevalence of interpersonal trauma exposure and PTSD in severely mentally ill patients is significantly higher than in the general population. For PA, SA, and PTSD, the prevalence rates differ depending on the type of mental disorder: lower rates of trauma are found for bipolar and major depressive disorder but higher rates are found for schizophrenia, BPD, and groups labelled as severely mentally ill. EA, EN, PN, complex PTSD, and dissociative disorders have been scarcely examined in SMI. Traumatized patients with SMI show more severe symptoms and a worse course of illness than non-traumatized patients with SMI.

**Acknowledgements**

This research was conducted as an internal project at GGNet Mental Health Centre to improve the treatment of complex trauma-related disorders in SMI.
