GABA and dopamine act directly on melanotropes of *Xenopus* to inhibit MSH secretion. BRAIN RES BULL 17(5) 697-704, 1986.-The release of melanophore stimulating hormone (MSH) from the pars intermedia of the amphibian *Xenopus laevis* is regulated by multiple factors of hypothalamic origin. The aim of this study was to determine if potential secretagogues function through a direct action on the melanotrope cell. For this purpose an *in vitro* superfusion system containing isolated melanotropes (cell suspension) was utilized. The viability of the cells in suspension was tested by examining their ability to synthesize, process and release pro-opiomelanocortin (POMC) related peptides. All biosynthetic functions appeared normal, with the exception that the isolated melanotropes are unable to N-terminally acetylate MSH. Release of immunoreactive-MSH from these cells was shown to be Ca²⁺-dependent, and high K⁺ stimulated release. Both the neurotransmitters dopamine and γ-aminobutyric acid (GABA), which are thought to be physiologically important MSH-release inhibiting factors, were shown to inhibit MSH release from isolated melanotropes. Dopamine appeared to function through a dopamine D2 type receptor mechanism while for GABA, both a GABAa and GABAb receptor mechanism are involved.

The regulation of dispersion of the black pigment melanin in dermal melanophores of amphibians is an example of a neuroendocrine reflex [1]. Most amphibians, when placed on a black background, release melanophore stimulating hormone (MSH) from the pars intermedia of the pituitary gland and consequently there is a darkening of the skin. While it is thought that central integration of the environmental input (color of background) would play an important role in determining the rate of MSH secretion, a consideration of the complexity of the innervation of the pars intermediate lobe itself may be an important factor in this integration. For example, in the aquatic toad *Xenopus laevis*, a dopaminergic system [24,25], an adrenergic system [9] and a GABAergic system [29] have been described within the pars intermedia. Moreover it has been shown that both dopamine [10,14] and α-adrenergic receptor agonists [28] as well as GABA [29] inhibit MSH release from incubated neurointermediate lobes of this species. In studies with intact neurointermediate lobe tissue the question arises if the secretagogues affect MSH release through an action directly on the melanotrope cells. The alternative is an indirect action, such as GABA induced release of dopamine, a phenomenon known to occur in the central nervous system [23]. To determine to what extent the pars intermedia melanotrope cell might be involved in integrating signals from the diverse neuronal systems within the neurointermediate lobe tissue, we are examining the effects of secretagogues on the release of immunoreactive MSH from isolated superfused melanotrope cells. The present study describes our preparation of melanotrope cell suspension and shows that both dopamine and GABA act directly on these cells.

**METHOD**

**Animals**

*Xenopus laevis* were bred and reared in our aquatic facility. Prior to the experiment the animals were kept for four weeks on a black background under constant illumination at 22°C.

**Preparation of Cell Suspension**

Neurointermediate lobes were extirpated, rinsed in incubation medium (IM) containing 112 mM NaCl, 2 mM KCl, 2

---

1This refereed paper was submitted in connection with a Symposium on "Multineuronal Control of the Intermediate Lobe of the Pituitary" as part of the Sixth European Winter Conference on Brain Research at Avoriaz, France, March 9-15, 1986. The Symposium was organized by H. Vaudry and G. Pelletier and supported by the University of Rouen (France), UCB Bioproduits Laboratories (Brussels, Belgium) and SANOFI (Toulouse, France).
FIG. 1. Comparison of viability of neurointermediate lobes and isolated intermediate lobe melanotropes of *Xenopus laevis*. Both intact tissue and cell suspension were given a 1 hr pulse-incubation in \[^{3}H\]lysine followed by a 3 hr chase incubation in medium containing L-lysine. Tissue extract, cell extract and chase incubation media were submitted to HPLC. The elution gradient (% secondary solvent, B) is given. Characterization of the newly synthesized peptides (numbered 1-VIII) has been reported earlier [19] and is summarized in the Results section. Arrows indicate a major difference between intact tissue and cell suspension, namely the relatively high contribution of product II to the incubation medium of the cell suspension. This product has been previously identified as desacetyl-oMSH.

The percentage of cell death was established with trypan blue and cell yield was estimated with a haemocytometer. Pars nervosa remnants were traced by cytochemical staining with anti-oxytocin.

**Pulse-Chase Incubation of Neurointermediate Lobe Tissue or Isolated Melanotropes**

Neurointermediate lobe tissue was extirpated, rinsed in IM and given a pulse incubation in 200 μl IM containing 40 μCi \[^{3}H\]lysine (75 Ci/mmol, Amersham), on a shaking water bath at 22°C. Tissue was rinsed in IM and chase incubated in 200 μl medium containing L-lysine (2 mM). It was then homogenized in 500 μl ice-cold 0.1 N HCl in a glass homogenizer and centrifuged (10 min, 10,000 g, 4°C). The supernatant was stored at -20°C before it was submitted to high performance liquid chromatography (HPLC) for separation of peptides. The incubation medium was acidified with 20 μl 1 N HCl and kept at -20°C before chromatography.

For pulse-chase analysis of cell suspensions, the cell-pellets were resuspended in 200 μl IM. Pulse incubation was started by addition of 100 μl IM, containing 40 μCi
HPLC Analysis of Radioactive Peptides

Peptides were separated on a spherisorb 10 ODS column (Chrompack, Middelburg, the Netherlands). The primary solvent was 0.5 M formic acid/0.14 M pyridine, pH 3.0 (A) and elution was accomplished with a gradient of n-propanol (B). The elution profile is indicated in Fig. 1. Fractions of 0.5 min were collected, 4 ml of scintillation fluid (Packard 199) were added for subsequent determination of radioactivity in a liquid scintillation counter.

Radioimmunoassay of αMSH

The C-terminal directed antiserum to αMSH was produced and characterized by Vaudry et al. [27]. It has equal reactivity to αMSH and desacetyl-αMSH. Bound and unbound MSH were separated by precipitation with polyethylene glycol (7.5%). Sensitivity threshold of the assay is 5 pg.

Superfusion of Isolated Melanotropes

Cells were suspended in a small volume of incubation medium and loaded in a 50 μl superfusion chamber with a millipore 0.45 μm filter (type HA) at the outlet to support a layer of biogel P2 (Bio仁). Following loading the chamber was filled with biogel. Medium was pumped with a peristaltic pump at a rate of 1.5 ml/hr and 7.5 min fractions were collected in 100 μl ice-cold 0.1 N HCl. Fractions were stored at −20°C before submission to radioimmunoassay. After an equilibration period of approximately 1 hr the effect of calcium-free medium with 0.5 M EGTA, or high K+ (osmolarity maintained by addition of NaCl) was established by giving 15 min pulses of the modified media. For comparative purposes the effect of high K+ on MSH release from intact neurointermediate lobe tissue was investigated. Lobes were placed in a 10 μl superfusion chamber and superfusion was performed as described earlier [28,29].

The effect of dopamine and/or GABA was investigated by giving 15 min pulses of these neurotransmitters to the superfused melanotropes. In additional experiments the dopamine D2-receptor antagonist sulpiride (Delagrange), the GABA agonists homotaurine (kindly provided by Dr. Maggi, Italy) and isoguvacine (Cambridge Research Biochemicals) and the GABAb agonist baclofen (Ciba Geigy) were used.

RESULTS

Analysis of Cell Suspension Viability

Average yield of cells was 18,000 per neurointermediate lobe. Microscopical analysis showed that the suspension consisted for the most part of individual cells with occasional cohesion of two or three cells. Percentage of cell death was estimated to be 15%. As judged from the anti-oxytocin cytochemical staining, the cell suspension was free of neural lobe fragments. The oxytocin positive material remained as intact tissue on top of the nylon filter.

Radiolabeled lysine was a convenient label for our initial biosynthetic analysis because this amino acid is present in all POMC-related peptides products of Xenopus melanotropes [16,19]. Shown in Fig. 1 are the results of pulse-chase analysis of intact neurointermediate lobe tissue and the cell suspension. The HPLC resolved peptides have been characterized earlier [19] to be: I, γMSH; II, desacetyl-αMSH; IV, co-eluting peptides αMSH and a form of corticotropin-like intermediate peptide (CLIP), designated CLIP I; V, a second form of CLIP, designated CLIP II; VI, unidentified; VII/VIII, peptides immunologically related to mammalian βendorphin and designated endorphin-like peptides. These earlier studies failed to identify βMSH. Sequence determination of Xenopus POMC-cDNA has revealed that βMSH is a potential biosynthetic product of Xenopus neurointer-

FIG. 2. Analysis of newly synthesized desacyl-αMSH (desAc-αMSH) and αMSH present in and released from intact neurointermediate lobes and isolated intermediate lobe melanotropes of Xenopus laevis. Neurointermediate lobes or the cell suspension were given a pulse incubation in [3H]tryptophan and a 3.5 hr chase incubation in medium containing L-tryptophan. Lobe extracts, cell extracts, and chase incubation media were then submitted to HPLC. The HPLC elution gradient is identical to that given in Fig. 1. Tissue and cell analyses are given in the upper profiles; analyses of incubation media are given in the lower profiles. Tryptophan labeled product II is desacetyl-αMSH, product IV is αMSH and product I represents the co-eluting peptides αMSH and βMSH.

Xenopus laevis.
mediate lobes [16], and indeed our subsequent analysis has shown that newly synthesized αMSH co-elutes with γMSH in a peak I (manuscript in preparation). Co-elution of two peptides may account for the relatively high CPM value associated with peak I.

The HPLC profile of newly synthesized lysine labeled peptides produced by and released from cell suspensions is very similar to that displayed by intact tissue with the notable exception of the relatively high contribution of product II (desacetyl-αMSH) to the incubation medium of the cell suspension (Fig. 1). To examine the biosynthesis of αMSH this experiment was repeated with [3H]-tryptophan as label (the CLIP peptide co-eluting with αMSH lacks tryptophan). The major tissue form of the newly synthesized αMSH related peptides is desacetyl-αMSH, although some αMSH is associated with the tissue (Fig. 2). The intact tissue secretes both desacetyl-αMSH and αMSH, but αMSH now makes a major contribution to the HPLC profile. For the cell suspension newly synthesized desacetyl-αMSH is both the major cellular and secretory form of αMSH related peptides. There is virtually no newly synthesized αMSH present (Fig. 2).

Analysis of Immunoreactive αMSH Related Peptides

Desacetyl-αMSH was the major form of immunoreactive MSH associated with both tissue (Fig. 3, left) and isolated cells (Fig. 3, right). Separate experiments (n=3) showed that the percentage of non-acetylated αMSH was 77±1.7% in intact tissue and 88±3.0% in isolated melanotropes.

HPLC analysis of immunoreactive MSH from incubation medium of intact tissue shows that desacetyl-αMSH and αMSH make an approximately equal contribution to the medium (Fig. 3, left). There is apparently a reduction of tissue stores of MSH during in vitro incubation, indicated by the fact that the amount of MSH in the tissue of the incubated lobe is only about 10% of that found in an unincubated neurointermediate lobe (Fig. 3, insert). Relative to intact tissue, the cell suspension had a low level of immunoreactive MSH (Fig. 3, right). These cells released predominantly the non-acetylated form of αMSH (Fig. 3).

MSH Release From Superfused Melanotropes

Superfused melanotropes had a tendency to show a slop-
FIG. 4. The release of immunoreactive MSH from superfused melanotropes of *Xenopus laevis*. Superfusion fractions were submitted to radioimmunoassay for αMSH. Short pulses (15 min) of Ca-free medium (containing 0.5 mM EGTA), medium containing 60 mM K⁺, or a combination of the two treatments were given as indicated in the figure. Insert: The effect of 60 mM K⁺ on the release of MSH from intact neurointermediate lobes. Black bar indicates those fractions where sulpiride (10⁻² M) was included in the superfusion medium. Results are expressed as percent basal release (±SEM, n=4); 100% basal release was defined in each experiment as the average amount of MSH in the three fractions preceding the first pulse of K⁺ (indicated by open circles).

FIG. 5. The effect of dopamine and GABA on the release of immunoreactive MSH from superfused melanotropes of *Xenopus laevis*. Results are expressed as percent basal release (±SEM, n=4). Open circles indicate those fractions used to determine 100% basal release. Superfusion conditions are described in Fig. 4.

FIG. 6. Effect of dopamine and the dopamine D₂-receptor antagonist sulpiride on the release of immunoreactive MSH from superfused melanotropes of *Xenopus laevis*. Superfusion conditions are described in Fig. 4.
ing base-line of MSH release (e.g., Fig. 1). Also, the rate of release of MSH could vary widely between different cell suspension preparations. The differences in absolute value of MSH released in different experiments precluded averaging of results and therefore, where we wished to combine results from more than one experiment, they are expressed as a percentage of the basal rate of release (e.g., Fig. 5). In this case the average level of MSH in the three superfusion fractions immediately preceding the pulse of secretagogue was defined as 100% basal release for each experiment, and within each experiment all MSH values in superfusion fractions were then expressed relative to this basal value.

The rate of release of \( \alpha \)-MSH from superfused cells was reduced by giving a short pulse of \( \text{Ca}^{2+} \)-free medium (Fig. 4). A pulse with medium containing 60 mM \( \text{K}^+ \) resulted in a dramatic increase in the amount of MSH found in the superfusion fractions. This contrasts sharply with the response of intact tissue to 60 mM \( \text{K}^+ \) (Fig. 4, insert), where the amount of MSH in the superfusion fractions decreases. Sulpiride had no effect on this \( \text{K}^+ \) induced inhibition of MSH release.

Both dopamine and \( \text{GABA} \) caused a clear reduction if the amount of MSH released to the superfusion medium (Fig. 5). The dopamine induced inhibition was very prolonged (Fig. 6), but could be reversed by sulpiride, a dopamine \( \text{D}_2 \)-receptor agonist. Both the \( \text{GABA} \) receptor agonist baclofen and the \( \text{GABA} \) receptor agonists isoguvacine and homotaurine are \( \text{GABA} \) receptor agonists. Superfusion conditions are described in Fig. 4. Open circles indicate those fractions used to determine 100% basal level of release.

**DISCUSSION**

The results of our biosynthetic studies indicate that the cell suspension constitutes a viable population of melanotropes. The only impairment we could detect was their inability to acetylate desacetyl-\( \alpha \)-MSH to form \( \alpha \)-MSH. This observation is interesting in that it has been shown that acetylation of MSH in the pars intermedia of *Xenopus laevis* is associated with the secretory process [18]. The failure of isolated cells to acetylate MSH may reflect the close association of this event with exocytosis. Possibly, the acetylation system is sensitive to minor perturbations of membrane structure or alterations in ionic environment. Another possible reason for the inability of isolated melanotropes to acetylate desacetyl-\( \alpha \)-MSH would be that the isolated melanotropes lack a physiological signal, which is necessary for the onset of the acetylation process. In separate experiments we have found that the degree of acetylation is probably regulated according to the background color to which the animal is adapted. The secretion-associated acetylation of intact tissue is reflected in the present results by the enhanced contribution of both newly synthesized \( \alpha \)-MSH and immunoreactive \( \alpha \)-MSH to the HPLC profile of incubation media relative to their contribution to the corresponding tissue profiles. The results indicate that while a small amount of intracellular acetylation is occurring, the non-acetylated peptide remains the major newly synthesized and immunoreactive tissue form of \( \alpha \)-MSH. In contrast, pulse-chase analysis with rat and mouse intermediate lobe tissue or cells show that desacetyl-\( \alpha \)-MSH is acetylated immediately following its biosynthesis [4, 5, 8, 11, 15]; not surprisingly, radioimmunoassay analysis of neurointermediate lobes of these species show that desacetyl-\( \alpha \)-MSH makes only a very minor contribution of acetylated forms of this peptide [2, 6, 11, 12, 22]. Goldman and Loh [7] have recently suggested that the major route for acetylation of MSH in the intermediate lobe of *Xenopus laevis* is comparable to the situation in mammals. In our opinion, the fact that desacetyl-\( \alpha \)-MSH is the major intracellular form of MSH in *Xenopus* makes such a comparison untenable.

As expected for a secretory process, the release of immunoreactive MSH from superfused melanotropes was found to be Ca\(^{2+}\)-dependent. The finding that high \( \text{K}^+ \) in the superfusion medium leads to a stimulation of the release of MSH was to be expected in that \( \text{K}^+ \) depolarizes cell membranes. More interesting is the response of intact tissue to high \( \text{K}^+ \), namely a complete inhibition of the secretion process. In that intact neurointermediate lobe tissue is rich in nerve terminals [3, 9, 20, 24, 25, 29], a good assumption is that high \( \text{K}^+ \) induces secretion of a factor or factors from these terminals which subsequently inhibit MSH secretion from the melanotrope. Indeed, we have found that high \( \text{K}^+ \) stimulates release of both dopamine and \( \text{GABA} \) from nerve terminals within the neurointermediate lobe tissue (unpublished observation). In view of the presence of at least these two inhibitory neurotransmitter systems within this tissue, it is not surprising that the dopamine receptor antagonist sulpiride failed to antagonize the \( \text{K}^+ \) induced inhibition of MSH-secretion. An important conclusion we can draw from the results with high \( \text{K}^+ \) is that the isolated melanotropes appear to be free of any interfering nerve terminals. Therefore, in our subsequent studies with these cells we consider that any effect of secretagogues on release of MSH from the superfused melanotropes is due to a direct action of the secretagogues on the melanotropes themselves.

Dopamine is an important MSH-inhibiting factor in both mammals and sub-mammalian species [1]. For *Xenopus laevis* it has been shown that this neurotransmitter is extremely potent in inhibiting release of both MSH [10, 14] and other POMC-related peptides [13, 17]. All these studies have been conducted with intact neurointermediate lobe tissue. The present results establish that, in inducing inhibition of MSH release, dopamine acts directly on the melanotrope

![Graph showing the effect of GABA receptor agonists on the release of immunoreactive MSH from superfused melanotropes of *Xenopus laevis*.](image-url)
cell. The observation that sulpiride, a specific D2 receptor antagonist, could reverse the dopamine induced inhibition indicates that Xenopus melanotropes possess dopamine receptors of the D2 type.

There are recent indications that the neurotransmitter GABA may also be of general importance as an MSH secretagogue. A GABAergic fiber network has been found throughout the pars intermedia of both the rat [21,31] and toad Xenopus laevis [29] and GABA has been shown to affect secretion of MSH in these species [26,29]. The response of Xenopus neurointermediate lobes to exogenous GABA is a very rapid inhibition of secretion of immunoreactive MSH [29]. Subsequent receptor characterization has shown that the Xenopus neurointermediate lobe tissue contains both GABAa and GABAb receptors. Activation of either of these receptors induces inhibition of in vitro MSH secretion.

It is apparent from the present results that the Xenopus laevis melanotrope cell itself possesses both the GABAa and the GABAb receptor. Receptor localization at the ultrastructural level will have to resolve whether independent GABAergic neuronal systems exist to independently utilize these two receptor mechanisms.

ACKNOWLEDGEMENTS

The authors wish to thank Drs. R. de Leeuw and H. Goos (University of Utrecht, The Netherlands) for their advice in preparing this manuscript; Dr. H. Vaudry (University of Rouen, France) for providing the antiserum; Mr. T. Aoyobi and Mr. P. M. J. M. Cruysen for technical assistance; Mr. R. E. Engels for the animal care; and Mrs. L. Jansen-Hoornweg for secretarial assistance.
