We study the charge-density dynamics within the two-dimensional extended Hubbard model in the presence of long-range Coulomb interaction across the metal-insulator transition point. To take into account strong correlations we start from self-consistent extended dynamical mean-field theory and include nonlocal dynamical vertex corrections through a ladder approximation to the polarization operator. This is necessary to fulfill charge conservation and to describe plasmons in the correlated state. The calculated plasmon spectra are qualitatively different from those in the random-phase approximation: they exhibit a spectral density transfer and a renormalized dispersion with enhanced deviation from the canonical $\sqrt{q}$ behavior. Both features are reminiscent of interaction induced changes found in single-electron spectra of strongly correlated systems.

discussion, see Refs. [25,26]). In two dimensions (2D), the potential decays as $V(q) \sim 1/q$, which leads to the “classical” $\omega_{p,\sigma}(q) \propto \sqrt{q}$ behavior of the plasmon dispersion with proportionality factor $\sqrt{2e^2n/m}$, with $n$ being the carrier density, $e$ and $m$ the charge and mass of the electron.

In EDMFT, both the single-particle self-energy $\Sigma$ and the polarization operator $\Pi$ are supposed to be local. While the former assumption yields a description of strong correlation physics in the manner of DMFT, the latter therefore leads to unphysical behavior of the collective charge excitations and to a divergence of the excitation energy in the long-wavelength limit [26]. In Ref. [25], the dual boson approach has been introduced as a diagrammatic extension of EDMFT. It allows us to restore the momentum dependence of the polarization operator through a ladder summation of diagrams. This scheme includes vertex corrections beyond the EDMFT $+$ $GW$ approximation. It is a minimal conserving approximation for correlated systems, similar to the RPA being the minimal theory for the Fermi gas. In this Letter, we employ this approach to study the charge excitations in two-dimensional correlated systems with long-range Coulomb interaction.

We proceed with the prototypical model of a strongly correlated system, the (extended) Hubbard model [5,6,27,28]

$$H = -t \sum_{\langle ij \rangle} c_{i\sigma}^\dagger c_{j\sigma} + \frac{1}{2} \sum_q V(q) \rho_{q^-q}, \quad \text{for } |q| > 0$$

on the two-dimensional square lattice with the charge susceptibility $X_\omega(q) = \langle pp \rangle_{q+q}$. In the above, $c_{i\sigma}^\dagger$ and $c_{i\sigma}$ denote the creation and annihilation of an electron on lattice site $i$ with spin $\sigma = \uparrow, \downarrow$ and $\rho_i = c_{i\uparrow}^\dagger c_{i\uparrow} + c_{i\downarrow}^\dagger c_{i\downarrow} - 1$ describes the deviation of the density at site $i$ from its average value 1 for the half-filled case that we consider. $t$ is the hopping parameter.

The long-range Coulomb interaction $V(q)$ has the form $U + V_0/|q|$ for $|q| > 0$ [29], where $V_0$ is the strength of the bare or effective screened interaction. Correlated adatom systems on semiconductor surfaces [30] and the plasmonics of graphene [31,32] provide beautiful examples of real phenomena which may be described within this model. The momentum dependent part corresponds to the asymptotic behavior of the Coulomb interaction in two dimensions for distances considerably larger than the interatomic distance and will result in a plasmonic branch [11–13]. For such distances, the long-range interaction is screened by the substrate and the potential strength is given by $V_0 = 2e^2/\kappa$, where $\kappa$ is the dielectric constant of the substrate [30].

In the following discussion, see Refs. [25,26]. In two dimensions (2D), the potential decays as $V(q) \sim 1/q$, which leads to the “classical” $\omega_{p,\sigma}(q) \propto \sqrt{q}$ behavior of the plasmon dispersion with proportionality factor $\sqrt{2e^2n/m}$, with $n$ being the carrier density, $e$ and $m$ the charge and mass of the electron.

In our calculations, we choose $4t = 1$ as the energy unit and work at fixed temperature $T = 0.02$ and $V_0 = 2$, while varying the parameter $U^* = U + 1.1$. In each case, we start from a standard, self-consistent EDMFT calculation. A hybridization expansion continuous-time quantum Monte Carlo solver [33,34] with improved estimators [35] is used to compute the imaginary-time correlation functions of the impurity model without approximation. In the final impurity solver step, we additionally compute the (reducible) impurity vertex function $\gamma_{\nu\omega}$ in the charge channel, where $\nu(\omega)$ are fermionic (bosonic) Matsubara frequencies. The polarization operator is represented in the form [25] $\Pi^{-1}_\omega(q) = \chi_\omega + \chi_{\omega\omega} \Pi_\omega(q) \chi_\omega^{-1} - U_{\omega\omega}$, where $\chi_\omega$ denotes the local charge susceptibility. The retarded interaction $U_{\omega\omega}$, which is the same as in EDMFT, describes the mean field screening of the local interaction. It contains the local part $U^*$ of the interaction and is treated on the level of the impurity model.

The dual bosonic self-energy $\tilde{\Pi}$ in turn is given by [cf. Fig. 1(a)]

$$\tilde{\Pi}_\omega(q) = \sum_{\nu\lambda\nu\lambda} \gamma_{\nu\lambda\omega\nu\lambda}\tilde{X}_\omega(q)\lambda_{\nu\omega}(q)$$

in EDMFT, it is identically zero). Here $\tilde{X}$ denotes the nonlocal part of the bubble. The vertex corrections in the dual boson approach enter through the renormalized triangular vertex [Fig. 1(b)]: $\Lambda_{\omega\omega}(q) = \lambda_{\omega\omega} + \sum_{\nu\lambda\nu\lambda\lambda} \Gamma_{\nu\lambda\omega\nu\lambda}\tilde{X}_\omega(q)\lambda_{\nu\lambda\omega}(q)\lambda_{\nu\omega}(q)$, where $\Gamma_{\nu\lambda\omega}(q)$ denotes the lattice vertex function in the particle-hole charge channel, which is obtained through the dual Bethe-Salpeter equation [25]. The Bethe-Salpeter equation generates ladder diagrams, which describe the repeated particle-hole scattering processes that give rise to the long-wavelength collective excitations.

In Fig. 2 we show the EDMFT local density of states (DOS) for the extended Hubbard model for three qualitatively different cases: For weak interaction $U^*$, the DOS exhibits a single quasiparticle peak at the Fermi level. As the interaction is increased, the peak is renormalized, as spectral weight is moved to incoherent excitations at a higher energy. This leads to the formation of Hubbard bands at energies $E \sim \pm U^*/2$. Above a critical $U^* \sim 2.4$, the system undergoes a first-order Mott transition [1,4]. The Hubbard bands persist in the Mott phase.

We now turn to the discussion of the results for the collective excitations. First, we verify in our numerical data that the polarization behaves as $q^2/(i\omega)^2$ for any finite Matsubara frequency $\omega_m > 0$ and small momenta [26]. We hence expect that an RPA-type analysis according to (1) still holds. In Fig. 3 we plot the inverse of the dielectric
function $\epsilon_\mathbf{q}(\mathbf{q}) = 1 + V(\mathbf{q})\Pi(\mathbf{q})$ as a function of real energy obtained by a stochastic analytical continuation procedure [36]. Despite the appearance of artifacts, the main qualitative features discussed here are robust. This quantity can be measured via angular resolved electron energy loss spectroscopy (EELS) [12,13]. We find that at $U^* = 1.1$, the overall behavior is reminiscent of the RPA. It can be understood within an itinerant electron picture. In the proximity of the $\Gamma$ point, the spectrum exhibits a single plasmon branch whose energy vanishes in the long-wavelength limit. We further see a rather well-defined but broadened excitation throughout the Brillouin zone with a wide continuum of particle-hole excitations below. The energy scales are determined by the hopping rather than the interaction, just as one would expect from a simple convolution of weakly renormalized Green's functions: The dominant contribution at the $M$ point stems from those $\mathbf{k}$ points connected by $M$ for which the single-particle dispersion $t_\mathbf{k}$ is extremal, corresponding to a large density of states. The energy difference is $t_M - t_\Gamma = 2$. At the $X$ point, $t_X - t_\Gamma = t_M - t_X = 1$. The energy scales are indeed found to be independent of $U^*$ in this regime.

At $U^* = 2.1$, the picture has changed drastically. The excitations of the particle-hole continuum are suppressed. More strikingly, the dispersion is split into two branches except for small wave vectors. The maximum energy of both branches is found at the $M$ point, where they are separated by a gap. The maximum of the lower branch is consistent with a value of $U^*/2$, while the latter is located at $E \sim U^*$. These features appear concomitantly with the Hubbard bands in the density of states of Fig. 2. One can interpret the lower branch to originate mainly from particle-hole excitations for which the electron is excited from the Hubbard band to the quasiparticle peak (or vice versa), whereas the upper branch stems from excitations between the Hubbard bands [37]. Similar splitting has also been observed in EDMFT $+ GW$ calculations for the extended Hubbard model with short-range interaction [23,24]. It is further apparent that the low energy, long wavelength excitations are renormalized in the vicinity of the $\Gamma$ point. This is expected for excitations from within the quasiparticle peak. We will discuss this feature in more detail below. The renormalization near the $\Gamma$ point and the splitting into two branches at the $M$ point are signs of a crossover from delocalized electrons in the metallic phase to the local physics in the insulating phase. At small energy scales electrons are characterized by their quasimomentum $\mathbf{k}$ and the Landau picture of interacting quasiparticles is valid at long wavelengths, so there is a plasmon branch in the metal. At larger energy scales, the whole density of states is relevant, including the Hubbard bands. Physically, the latter reflects atomlike, localized features of strongly correlated electrons.

Figure 3 finally shows the inverse dielectric function in the Mott insulator at $U^* = 2.6$. In this state, a two-particle excitation corresponds to a creation of a doublon and a holon, which costs an energy $U^*$. Such an excitation is expected to be highly localized. As a result, we see a weakly dispersing branch at an energy $E \sim U^*$. The low-energy plasmon mode has disappeared together with the quasiparticle peak.

Similar to the single-particle spectra of correlated systems, we observe a spectral weight transfer in the plasmon spectra. This is clearly illustrated in Fig. 4, where we show the inverse dielectric function for fixed momentum.

FIG. 2 (color online). Finite temperature local density of states of the two-dimensional Hubbard model with long-range Coulomb interaction calculated within EDMFT. The local interaction $U^*$ moves spectral weight from the quasiparticle peak at the Fermi energy to the Hubbard bands at $E \sim \pm U^*/2$. For sufficiently large $U^*$, the system is a Mott insulator.

FIG. 3 (color online). Inverse dielectric function $-\text{Im}\epsilon^{-1}_\mathbf{q}(\mathbf{q})$ of the 2D Hubbard model with long-range Coulomb interaction for different values of the effective local interaction $U^*$ across the Mott transition. The spectra show a transition from itinerant to localized behavior. The interaction causes a spectral weight transfer as well as a renormalization of the long-wavelength plasmon dispersion. The dispersion relation $\omega_p(\mathbf{q})^2 = \alpha V_0 q$ is shown in white.
The respective values of $U^*$ are indicated, showing that the spectral weight transfer is indeed associated with this energy scale.

The interaction also has significant impact on the plasmon dispersion. In graphene or in other systems with nonparabolic energy bands, there is a rescaling of the plasmon spectrum [38]. Evidence for a correlation-induced departure from the $\sqrt{q}$ behavior at finite $q$ has been reported in Ref. [39]. Fermi liquid theory allows a renormalization of the plasmon dispersion in systems with broken Galilean invariance, but can only provide predictions in the long wavelength limit. We now illustrate how the interaction renormalizes the dispersion for finite wave vectors.

At small $q$ the polarization operator is, to lowest order, proportional to $(q/E)^2$: $\Pi_E(q) = -\alpha(q/E)^2 + \cdots$ (see Supplemental Material [40] for additional details). The plasmon dispersion can then be expressed using Eq. (1):

$$\omega_p^2(q) = \alpha V_0 q + \cdots.$$  

We find that the effect of the interaction is to significantly lower the value of $\alpha$ and has two main effects. First, the value of the plasma frequency $\omega_p$ is renormalized: For the RPA with $U^* = 1.1$ and the dual boson results with $U^* = 1.1$ and $U^* = 2.1$, we find $\alpha_{\text{RPA}} \approx 0.2$, $\alpha_{U^*=1.1} = 0.16 \pm 0.02$ and $\alpha_{U^*=2.1} \approx 0.07 \pm 0.03$, respectively. Compared to RPA, the plasma frequency is hence renormalized for small $q$ by a factor $\sqrt{\alpha_{U^*=1.1}/\alpha_{\text{RPA}}} \approx 0.9$ and hence reduced by $10\%$ by the dynamical vertex corrections included beyond the RPA. Comparing the cases $U^* = 1.1$ ($U = 0$) and $U^* = 2.1$ ($U = 1$) we obtain $\sqrt{\alpha_{U^*=2.1}/\alpha_{U^*=1.1}} \approx 0.66$, a decrease by more than $30\%$ induced by on-site correlations. We find that while the plasma frequency decreases as the Mott transition is approached, the renormalization does not scale with the quasiparticle weight $Z = (1 - d\text{Re}\Sigma_0/da)^{-1}$ [26], contrary to what one might naively expect for particle-hole excitations within the quasiparticle peak. This implies that plasmons are considerably affected by the incoherent (nonquasiparticle) properties of the system. This is consistent with the observation that the spectrum in the middle panel of Fig. 3 cannot be described in terms of a simple convolution of renormalized Green’s functions. Because of the internal summation over all fermionic frequencies in the particle-hole bubble that appears between the scattering events in the Bethe-Salpeter equation, the quasiparticles and holes probe the entire energy spectrum. The collective excitations are hence influenced by the high energy scales (Hubbard bands). Second, the interaction enhances the deviation from the $\omega_p(q) \sim \sqrt{q}$ dispersion. This can be seen in Fig. 5, where we plot the plasmon dispersion (3) (solid lines) [41] together with the pure $\omega_p^2 = aV_0 q$ form. The interaction clearly causes the dispersion to depart from the $\sqrt{q}$ behavior at significantly smaller wave vectors.

We expect the spectral weight transfer and the dispersion renormalization to be general features of plasmons in strongly correlated systems. The spectral density transfer leads to qualitative differences in the EELS below and above $U_c$. For the particular case of the unfrustrated half-filled Hubbard model on the square lattice, strong antiferromagnetic correlations can also be taken into account, as they lead to a pseudogap [42] and may open the gap at any finite $U$ for $T \to 0$ [43]. These effects may alter our results at low temperatures. Plasmons with energies larger than the gap can, however, be expected to be unaffected by the antiferromagnetism.

In summary, we have studied the evolution of the collective charge excitations across the Mott metal-insulator transition. By means of a ladder diagram summation, we included local as well as nonlocal vertex corrections to the polarization within the dual boson approach. This is essential to fulfill the requirement of local charge conservation, thus providing the $q^2/\omega^2$ behavior of the polarization operator in the long wavelength limit. It allows us to describe the collective excitations in the correlated state. We have shown that an RPA-type analysis of the long wavelength excitations remains valid in the correlated regime. The dispersion of these long wavelength excitations is however strongly renormalized by the interaction. The renormalization is found not to scale with the quasiparticle weight, showing that plasmons are affected by incoherent properties in an essential way. Strong correlations further lead to a spectral weight transfer of...
the plasmonic modes, which cannot be described within the RPA. Spectral weight transfer and dispersion renormalization provoke an association of the analogous phenomena observed in single-particle spectra of strongly correlated systems. Theoretical and experimental studies of plasmons in correlated materials, for example, focusing on the mutual interplay between charge and spin degrees of freedom like in correlated materials, for example, focusing on the mutual
