PURPOSE. To provide a clinical and genetic description of a patient cohort with Stargardt disease (STGD1) with identifiable foveal sparing.

METHODS. Patients with retinal atrophy (defined as an absence of autofluorescence) that surrounded the fovea by at least 180° and did not include the fovea were defined as having foveal sparing; eyes with visual acuity (VA) worse than 20/200 were excluded. We reviewed the medical files and extracted data regarding medical history, VA, ophthalmoscopy, static perimetry, fundus photography, spectral-domain optical coherence tomography (SD-OCT), fluorescein angiography (FA), fundus autofluorescence (FAF), and electroretinography (ERG). We screened each patient’s ABCA4 gene for mutations.

RESULTS. Seventeen eyes with foveal sparing were identified in 13 unrelated patients. In 4 eyes, the fovea gradually became atrophic after the initial foveal sparing. The mean age at onset was 51 years (range, 32–67 years). Visual acuity was 20/40 or better in all foveal sparing eyes and was 20/25 or better in 41%. Fundus autofluorescence imaging revealed hyperautofluorescent flecks and parafoveal retinal atrophy; SD-OCT revealed sharply delineated atrophy; and perimetry revealed parafoveal scotomas with intact foveal sensitivity. Finally, genetic screening identified mutations in 19 of the 26 ABCA4 gene alleles.

CONCLUSIONS. Foveal sparing occurs mainly in patients with late-onset STGD1 and represents the milder end of the clinical spectrum in STGD1. The anatomy, metabolism, and biochemistry of the retina, as well as genetic variations in genes other than ABCA4, can influence the etiology of foveal sparing. Identifying these fovea-protecting factors will facilitate the future development of strategies designed to treat STGD1.

Keywords: foveal sparing, Stargardt disease, ABCA4

Within the retina, the macula provides the highest visual acuity and contains the highest density of cones. Therefore, a loss of central vision is a hallmark feature of macular dystrophies. There are, however, exceptions to this rule. Foveal sparing is an intriguing phenomenon in which retinal atrophy surrounds a relatively preserved fovea, leaving central visual acuity largely unaffected. Although foveal sparing has been reported in a variety of conditions, including Stargardt disease (STGD1), mitochondrial retinal dystrophy associated with the m.3243A>G mutation, and geographic atrophy in age-related macular degeneration (AMD), its etiology remains poorly understood.

Stargardt disease is an autosomal recessive retinal dystrophy that typically presents within the first two decades of life. Although the clinical presentation of STGD1 varies widely, it is usually characterized by a progressive loss of central vision, irregular yellow-white fundus flecks, and the so-called beaten bronze atrophic macular lesions. Stargardt disease has been linked to mutations in the ABCA4 gene, which encodes an adenosine triphosphate (ATP)-binding cassette transporter (ABCR) expressed specifically in the cones and rods of the retina. Defects in ABCR function cause the accumulation of all-trans-retinal and its cytotoxic derivatives (e.g., diretinoid-pyridinium-ethanolamine) in photoreceptors and retinal pigment epithelial (RPE) cells, ultimately causing RPE cell death and the subsequent loss of photoreceptors.

Mutations in ABCA4 have been linked to a spectrum of phenotypes ranging from mild macular dystrophy to severe early-onset panretinal dystrophy. We previously postulated that disease severity may be correlated with the functional severity of the particular mutation in the resulting ABCR protein. The substantial clinical variability among patients with STGD1—including an age at onset of the symptoms that can range from 5 to 72 years of age, diverse fundoscopic features, diverse electrophysiological findings, and a variable time course of vision loss—suggests the presence of several strong modifying factors.

Recently, Fujinami et al. reported the clinical and molecular genetic findings of a cohort of STGD1 patients with relatively preserved foveal structure and function (based on seemingly normal autofluorescence at the fovea). Their study revealed the presence of two basic—yet distinct—STGD1 phenotypes, namely STGD1 patients with foveal sparing and STGD1 patients with early-onset foveal atrophy. However, the onset of foveal involvement in STGD1 can vary substantially and can occur in later disease stages, for example, in late-onset...
This heterogeneity complicates the selection of homogeneous cohorts for clinical studies to investigate the subtype of STGD1 patients with foveal sparing. Here, we report the clinical characteristics and the natural course of foveal sparing in a cohort of STGD1 patients with foveal sparing, and we explore the mechanisms that may underlie this phenomenon.

**METHODS**

**Patients and Genetic Analysis**

The patient selection process is depicted in Figure 1. The database of the Department of Ophthalmology at Radboud University Medical Center (Nijmegen, The Netherlands) contains 425 clinically suspected cases of STGD1. For 257 of these patients, an ABCA4 genetic screen for known mutations was performed in the Department of Human Genetics at Radboud University Medical Center using arrayed primer extension analysis (APEX) microarrays (Asper Biotech, Tartu, Estonia). Because STGD1 is autosomal recessive, if the APEX microarray screen revealed only one mutation in a given patient, we sequenced the exons and intron-exon boundaries in ABCA4 to identify the mutation in the second allele. All mutations were confirmed using Sanger sequencing. The presence of one or two mutations in the ABCA4 gene confirmed the diagnosis of STGD1 in 198 patients. For our study, we selected cases in which foveal sparing was documented using fundus photography and/or fundus autofluorescence (FAF) imaging. Patients with RPE atrophy (defined as an absence of autofluorescence surrounding the fovea by least 180°) that did not include the fovea were defined as having foveal sparing. Eyes with visual acuity of 20/200 or worse were presumed to have little or no foveal function and were therefore excluded. Twelve unrelated STGD1 patients with foveal sparing in at least one eye were included in this study. We also included one additional patient who initially presented with foveal sparing; in this patient, the fovea became atrophic as the disease progressed. To exclude pseudo-Stargardt pattern dystrophy,27 the PRPH2 gene was sequenced in all 13 patients.

This study was performed in accordance with the tenets of the Declaration of Helsinki, and all participating patients gave their informed consent prior to providing a blood sample and receiving additional ophthalmologic examinations.

**Clinical Examination**

Clinical data were collected from the medical records of the 13 eligible patients. The data collected included the patient’s age at onset, medical history, initial symptoms, and the overall course of the retinal disorder. Age at onset was defined as the age at which the initial symptoms were noted by the patient. We defined the duration of symptomatic disease as the time from the age at onset to the patient’s current age. In the patients who were initially asymptomatic, the age at their first visit to the ophthalmologist was used to define duration.

The standard ophthalmic examination included a measurement of best-corrected visual acuity (BCVA) using Snellen visual acuity charts and ophthalmoscopy. The central visual field was assessed with a Humphrey perimeter (Carl Zeiss Meditec, Jena, Germany) using central 10-2, 24-2, or 30-2 threshold tests in two, two, and four patients, respectively. Fundus photography (Topcon TRC50IX; Topcon Corporation, Tokyo, Japan) was performed in 10 patients. Fluorescein angiography (FA) was performed in 10 patients to screen for the presence of the dark choroid sign. Full-field electroretinography (fERG; 8 patients) and multifocal ERG (mfERG; 7 patients) were performed using Dawson-Trick-Litzkow (DTL) electrodes and the RETI-port system (Roland Consults, Tachische & Finger GmbH, Brandenburg an der Havel, Germany). Both the fERG and mfERG recordings were performed in accordance with the guidelines of the International Society for Clinical Electrophysiology of Vision (ISCEV).28

Cross-sectional images were obtained using spectral-domain optical coherence tomography (SD-OCT; Heidelberg Engineering, Heidelberg, Germany) in 12 patients; a 20° × 15° 19-line scan covering the fovea was used. Total retinal thickness, outer nuclear layer (ONL) thickness, and photoreceptor–RPE (PR–RPE) complex thickness were measured at the foveal dip and at 0.25-, 0.5-, 1-, 1.5-, 2-, and 2.5-mm eccentric distances using Heidelberg Eye Explorer software (Version 1.6.4.6; Heidelberg Engineering). Outer nuclear layer thickness
was measured from the outer plexiform layer to the external limiting membrane (ELM); PRþRPE thickness was measured from the ELM to Bruch’s membrane; and total retinal thickness was measured from the vitreous–retinal interface to RPE–limiting membrane (ELM); PRþRPE layers was normal at the foveal center in most patients. However, in the parafoveal region, the photopic and scotopic amplitudes were reduced more markedly than the amplitude of photopic flash responses, although none of these patients had peripheral pigmentary retinopathy. No clear correlation was found between fERG response and disease duration, visual acuity, or fundoscopic characteristics. We also measured mfERG in eight eyes with foveal sparing and found that the P1-response amplitudes in the central two rings (representing the foveal retina) were relatively intact compared to the outer three rings, which showed severely reduced responses.

**Retinal Structure**

Spectral-domain OCT imaging was performed in 12 patients and revealed highly localized damage to the lamellar architecture of the macula. We observed parapapillary atrophy of photoreceptors and RPE cells with sharp borders, represented by a loss of the bands associated with the ELM, the ellipsoid inner segments, and the RPE (Figs. 5B–5D). These bands were present in the fovea, however, although many of the bands that corresponded to the ellipsoid inner segments were irregular. In addition, the longer outer segments—which are characteristic of cone photoreceptors in the foveal dip—were not observed in any of these 12 eyes (Figs. 5A–5D). In three eyes, we observed signs reminiscent of outer retinal tubulation at the border of the atrophic lesions (Fig. 5D), although no rosette-like structures (as described by Zweifel and colleagues) were observed. Micronodular macular edema was present in three eyes (Fig. 5C), and epiretinal gliosis with retinal wrinkling extending over the fovea was observed in one eye.

An analysis of the retinal lamellar architecture revealed that the overall retinal thickness in the foveal and parafoveal regions was generally decreased (Fig. 5F). The thickness of both the ONL and PRþRPE layers was normal at the foveal center in most patients. However, in the parafoveal region, the PRþRPE was usually nearly absent, whereas the ONL was progressively thinner in this region (Fig. 5F).

**Natural Course of Foveal Sparing**

An analysis of the longitudinal FAF data, which were available for six patients, enabled us to investigate the natural course of foveal sparing. In general, fundus flavimaculatus flecks were observed in the early stages, in some cases even before symptoms developed. Within one to two decades of diagnosis...

range, 10–18 years), one or more sharply delineated parafoveal RPE atrophic areas appeared (Fig. 4A). Over time, these lesions expanded and reached confluence around the fovea, thus producing the foveal sparing phenotype. We observed three distinct stages in the development of foveal sparing; these stages characterize the natural course of the phenomenon. In stage 1, parafoveal atrophic lesions emerge, with several intact RPE connections between the fovea and the surrounding vital RPE (Figs. 4A, 4C). In stage 2, the atrophic RPE lesions interconnect, leaving only a single isthmus of RPE, thus resulting in a “peninsula-like” appearance (Figs. 4E, 4G). Stage 3 is characterized by an isolated fovea that is surrounded completely by RPE atrophy (Figs. 4I, 4K). We measured the expansion rate of the atrophic lesions in four patients using the FAF follow-up data (Table 3). The rate of expansion ranged from 0.832 to 2.363 mm²/y in these patients, and the rate was positively correlated to the size of the atrophic lesions. Given this wide range of expansion rates, it is unclear how long foveal sparing is present before the foveal structure and function become significantly affected by the profound atrophy; however, we observed that the foveal structure and function were relatively preserved for up to 6
years in patients 8 and 12. Eventually, the remaining foveal tissue became progressively smaller and atrophy of the central fovea was observed in four eyes (in patients 10, 11, and 12; Figs. 4L, 4N, 5E); this was accompanied by a decline in central vision to 20/200 or worse.

**Genetic Analysis and Mutation Screening**

An examination of the pedigrees of the 13 unrelated patients with foveal sparing revealed a recessive inheritance pattern in five patients; the other eight patients appeared to be isolated cases. Mutations in the \( \text{ABCA4} \) gene were identified in 19 of the 26 alleles (73%, Table 2). We identified compound heterozygous mutations in six patients (46%) and single heterozygous mutations in the other seven patients (54%). In total, 13 different \( \text{ABCA4} \) variants were identified, including nine missense mutations, two splice site mutations, one nonsense mutation, and one synonymous variant that affects splicing. Each of these variants has been described previously (Table 2).

The mutational effects of five of the identified mutations have been reported previously (Supplementary Table S1). Although functional data regarding the effects of the other eight mutations is not available, we can speculate on the functional effect of the nonsense mutation (p.Gln1292*). Assuming that the resulting mRNA is not subject to nonsense-mediated decay, the resulting truncated protein will lack the second extracytoplasmic domain and the nucleotide-binding domain, which are involved in substrate and ATP binding, respectively. Supplementary Table S2 summarizes the identified missense mutations in \( \text{ABCA4} \), including allele frequencies in the exome variant server (EVS) and scores obtained from selected predictive tools. No differences in phenotype were observed between patients carrying severe mutations and patients carrying mild mutations. Finally, no pathogenic mutations in the \( \text{PRPH2} \) gene were identified in this cohort, thereby excluding the possibility of pseudo-Stargardt pattern dystrophy.

**Discussion**

Here, we present the clinical characteristics of 13 STGD1 patients with foveal sparing in one or both eyes. The majority of these patients were diagnosed with late-onset STGD1; only 5 patients developed symptoms prior to the age of 45 (Table 1).

In eyes with foveal sparing, visual acuity was relatively preserved; nevertheless, most of the patients experienced some loss of vision, which caused them to seek ophthalmologic care. In these instances, ophthalmoscopy readily revealed advanced retinal disease, with yellow-white irregular pisciform flecks and profound RPE atrophy adjacent to the fovea. Automated perimetry revealed perifoveal scotomas of various sizes with intact foveal sensibility. This combination of mild vision loss together with profound retinal abnormalities is typical among STGD1 patients with foveal sparing.

Recently, Fujinami et al.\(^6\) reported the clinical and molecular findings of a cohort of Stargardt patients with a foveal sparing phenotype. In their study, the authors included STGD1 patients with a functional fovea, irrespective of the presence of parafoveal RPE atrophy; thus, they studied a heterogeneous cohort of 40 patients. In contrast, in our cohort we defined foveal sparing as profound RPE atrophy that surrounded the fovea by at least 180\(^\circ\) and spared the fovea's structure and function. This clinical presentation is a rare finding among STGD1 patients, and our strict selection criterion resulted in a small but homogeneous cohort with a consistent phenotype and excluded STGD1 patients with late-onset disease that began with foveal atrophy. Moreover, our definition of foveal sparing is consistent with previously reported cases of foveal sparing in patients with other degenerative diseases.\(^6,8,35,34\) Despite the differences between our cohort and the cohort described by Fujinami et al.,\(^6\) the visual acuity and electrophysiology findings in their paper are similar to the findings in our study; nevertheless, none of our patients were carriers of the \( \text{ABCA4} \) p.Arg2030Gln missense mutation, which was suggested previously to be prevalent among STGD1 patients with foveal sparing.\(^26\)

**The Etiology of Foveal Sparing**

In our study, screening the \( \text{ABCA4} \) gene identified 19 pathogenic mutations that were described previously in STGD1 and/or other \( \text{ABCA4} \)-associated retinopathies (Table 2).\(^{20,25,35–45}\) Interestingly, however, foveal sparing was not described in any of the patients who were previously reported to carry these mutations. In a previously proposed model that links phenotype severity to the degree of residual ABCR function,\(^23,31\) late-onset STGD1 with foveal sparing was placed at the mild end of the spectrum of \( \text{ABCA4} \)-associated retinopathies.\(^3\) Indeed, none of our STGD1 patients with foveal sparing had two \( \text{ABCA4} \) variants that are associated with
FIGURE 4. Natural course of fundus and perimetric changes in STGD1 with foveal sparing. FAF imaging can be used to identify the three stages that occur in foveal sparing. In stage 1, confluent parafoveal RPE lesions surround the macula, leaving several connections of intact RPE with the surrounding vital RPE (stage 1 (A, C)). Over time, the RPE atrophy progresses, and the lesions interconnect, leaving only one isthmus of RPE (stage 2 (E, G)). Further disease progression leads to an isolated fovea that is surrounded completely by RPE atrophy (stage 3 (I, K)). Eventually, RPE atrophy overcomes foveal resistance, leading to foveal degeneration (post foveal sparing (L, N)). Static perimetry examination reveals absolute perifoveal scotomas with intact foveal sensitivity in all eyes with foveal sparing (B, D, F, J). Large absolute scotomas with diminished foveal sensitivity were observed in the eyes post foveal sparing (M, O). (A, B) FAF (A) and 24-2 perimeter (B) in patient 13 at age 63. (C, D) FAF (C) and 30-2 perimeter (D) in patient 4 at age 60 and 61, respectively. (E, F) FAF (E) and 10-2 perimeter (F) in patient 3 at age 64 and 65, respectively. (G, H) FAF (G) and 24-2 perimeter (H) in patient 5 at age 45. (I, J) FAF (I) and 50-2 perimeter (J) in patient 8 at age 66 and 65, respectively. (K) FAF in patient 6 at age 58. a severe loss of ABCR function. However, our knowledge regarding the functional consequences of ABCA4 mutations identified to date is limited (Supplementary Table S1). It can be extremely difficult to assess the effect of most missense variants using in silico predictions and allele frequencies in healthy individuals, for whom this information is often incomplete (Supplementary Table S2); in addition, assessing the combined effect of carrying two ABCA4 variants is

*Measurements were performed by two authors (RACvH and NMB), and the average of the two measurements is shown. Mean interobserver variance was 2.7% (range, 0.4%-9.8%).
particularly difficult. Functional assays are needed in order to
form definitive conclusions regarding the effects of these
mutations.

Because foveal sparing can be present in phenotypes that
are independent of ABCA4 mutations, including AMD and
mitochondrial retinal dystrophy,5,8–12,17,20,25,44–45 some
gene factors other than ABCA4 mutations are likely involved.
These factors could include single nucleotide polymorphisms
(SNPs) and even mutations in retina-specific genes other than
ABCA4, which suggests that a digenic or triallelic trait—in
g combination with the identified ABCA4 mutations—may underlie
the degenerative pattern observed in our patients. Moreover,
anatomical, metabolic, and/or biochemical factors may under-
lie foveal sparing. For example, the average peak density of
cones in the fovea is 199,000 cones/mm², but can range from
98,200 to 324,100 cones/mm².2 The initial number of cones in
the fovea may play a role in the development of foveal sparing;
however, adaptive optics imaging techniques—which can
provide the resolution needed to determine photoreceptor
density in vivo—are not generally available in most ophthal-
mology practices. Another factor to consider is that S (“blue”)
cone photoreceptors, which are absent in the foveal center,
seem to be more vulnerable to retinal disease than M and L
cones, although this selective vulnerability has not been
reported in STGD1.46–47 Moreover, parafoveal rods appear to
be more vulnerable than cones to the effects of aging and all-
trans-retinal–mediated damage.48–50 This difference may arise
from the sole dependence of rods on the RPE for replenishing
11-cis-retinal; in contrast, cones are also supplied by Müller
cells.51 Furthermore, cone cells have a slower turnover rate of
outer segments compared to rods,52 although this does not
necessarily result in higher all-trans-retinal levels in RPE cells,
as regeneration is faster in cones than in rods.53 Macular
pigments, which can filter out high-energy light, may also serve
a protective role, given that light exposure is crucial in the
pathogenesis of STGD1.53,54 In addition, rod-derived cone
viability factor (RdCVF), which is believed to prevent cone
degeneration,55 may also play a role. Importantly, the absolute
levels of macular pigments and RdCVF may differ between
STGD1 patients with foveal sparing and STGD1 patients
without foveal sparing.

Differential Diagnosis and Clinical Significance of
Foveal Sparing

When forming a diagnosis, foveal sparing–associated clinical
entities other than late-onset STGD should be considered,
including geographic atrophy in AMD, mitochondrial retinal
dystrophy associated with the m.3243A>G mutation, central
areolar choroidal dystrophy, and pseudo-Stargardt pattern
dystrophy.5,9,10,27 Importantly, misdiagnosing this condition
can lead to inappropriate genetic counseling (these diseases
display unique inheritance patterns) and/or an inaccurate
estimate of the prognosis. Furthermore, in the event of an
incorrect diagnosis of AMD, prescribing vitamin A–rich
nutritional supplements can accelerate the accumulation of
all-trans-retinal–derived toxins and increase the rate of disease
progression, as shown in the retinas of homozygous Abca4
knockout mice.56 Stargardt disease with foveal sparing can be
diagnosed based on the presence of characteristic pisciform
flecks together with RPE atrophy surrounding the fovea, a
“dark choroid” sign on FA, and genetic analysis of the ABCA4
gene. Fundus autofluorescence imaging can clearly highlight
the fundus flecks, which appear as hyperautofluorescent
flecks, and RPE atrophy, which appears as an absence of
autofluorescence. Retinal dystrophies that closely resemble
STGD1 can follow other patterns of inheritance—for example,
due to mutations in mitochondrial DNA—or can be autosomal
dominant, with variable penetrance and expression. The fact
that the dark choroid sign is present in approximately 85% of
patients with STGD157 suggests a pivotal role for genetic
analysis in the diagnosis of retinal dystrophies.

In conclusion, foveal sparing is a clinical phenomenon that
occurs primarily in patients with late-onset STGD1 and is
associated with the relative preservation of visual acuity,
although visual acuity ultimately deteriorates by the end stage
of the disease. Stargardt disease patients with foveal sparing
may be promising candidates for future therapeutic trials, as
delayed degeneration of the fovea increases the time window
for applying therapeutic interventions such as gene therapy.
Although the mechanisms that underlie foveal sparing are
currently unclear, expanding our knowledge of the metabolic
and biochemical processes that lead to foveal sparing can
facilitate the development of therapeutic strategies aimed at
preserving foveal function.

Acknowledgments

We thank all of the patients for their participation in this study.
Additionally, we thank Michel M. Teussink, MSc, for his assistance
with MathLab. We also thank Odette A.M. Tigchelaar-Besling, MD,
for sharing her clinical observations.
