Search for a new resonance decaying to a $W$ or $Z$ boson and a Higgs boson in the $\ell\ell/\ell\nu/\nu\nu + b\bar{b}$ final states with the ATLAS detector

ATLAS Collaboration

CERN, 1211 Geneva 23, Switzerland

Abstract A search for a new resonance decaying to a $W$ or $Z$ boson and a Higgs boson in the $\ell\ell/\ell\nu/\nu\nu + b\bar{b}$ final states is performed using 20.3 fb$^{-1}$ of $pp$ collision data recorded at $\sqrt{s} = 8$ TeV with the ATLAS detector at the Large Hadron Collider. The search is conducted by examining the $WH/ZH$ invariant mass distribution for a localized excess. No significant deviation from the Standard Model background prediction is observed. The results are interpreted in terms of constraints on the Minimal Walking Technicolor model and on a simplified approach based on a phenomenological Lagrangian of Heavy Vector Triplets.

1 Introduction

Although the Higgs boson discovery by the ATLAS [1] and CMS [2] collaborations imposes strong constraints on theories beyond the Standard Model (SM), the extreme fine tuning in quantum corrections required to have a light fundamental Higgs boson [3,4] suggests that the SM may be incomplete, and not valid beyond a scale of a few TeV. Various dynamical electroweak symmetry breaking scenarios which attempt to solve this naturalness problem, such as Minimal Walking Technicolor [5–8], Little Higgs [9], or composite Higgs models [10,11], predict the existence of new resonances decaying to a vector boson plus a Higgs boson.

Using the full dataset collected by the ATLAS detector at 8 TeV centre-of-mass energy at the Large Hadron Collider, a search is performed for a heavy resonance decaying to $VH$, where $V$ is a $W$ or $Z$ boson and $H$ is the SM Higgs boson. This analysis looks for the leptonic decay of the $W$ or $Z$ boson and the Higgs decay into a $b\bar{b}$-quark pair. Therefore the selected final states are: zero charged leptons targeting $Z(\rightarrow \nu\nu)b\bar{b}$ decays, one charged lepton $W(\rightarrow \ell\nu)b\bar{b}$, and two oppositely charged leptons $Z(\rightarrow \ell\ell)b\bar{b}$ where $\ell = e, \mu$. The search is performed by examining the distribution of the reconstructed $VH$ mass ($m_{VH}$) for a localized excess. The signal strength and the background normalization are determined from a likelihood fit to the data distribution in the three channels studied.

As a benchmark, the Minimal Walking Technicolor model (MWT) is used, a model with strongly coupled dynamics. This model predicts two triplets of resonances, $R_{1}^{\pm,0}$ and $R_{2}^{\pm,0}$, one of which is a vector and the other an axial-vector, that couple to vector bosons with strength $g$ and to fermions with $g'/g$, where $g$ is the weak SU(2) coupling constant. The bare axial-vector mass $m_{A}$ determines the masses of $R_{1}$ and $R_{2}$, with the lower mass resonance $R_{1}$ having a mass close to $m_{A}$. Recent lattice simulations in this model [12–14] predict masses close to 2 TeV. The decay channels $R_{1,2}^{\pm,0} \rightarrow WH$ and $R_{1,2}^{0,0} \rightarrow ZH$, lead to $Wb\bar{b}$ and $Zb\bar{b}$ final states.

A simplified approach based on a phenomenological Lagrangian [15] that incorporates Heavy Vector Triplets (HVT), which allows the interpretation of the results in a model-independent way, is also used. Here, the new heavy vector bosons, $V^{\pm,0}$, couple to the Higgs and SM gauge bosons via a combination of parameters $g_{VCH}$ and to the fermions via the combination $(g^2/g_V) c_F$. The parameter $g_V$ represents the strength of the new vector boson interaction, while $c_H$ and $c_F$, which represent the couplings to the Higgs and the fermions respectively, are expected to be of order unity in most models. Two benchmark models [15] are used here. In the first model, referred to as model $A$, the branching fractions to fermions and gauge bosons are comparable, as in some extensions of the SM gauge group [16]. For model $B$, fermionic couplings are suppressed, as for example in a composite Higgs model [17].

The three final states presented in this Letter have been extensively studied for non-resonant production in ATLAS [18]. Moreover, a search for a pseudoscalar resonance in the $\ell\ell b\bar{b}$ and $\nu\nu b\bar{b}$ channels has already been published by ATLAS, setting limits on two-Higgs-doublet models [19]. Other searches for particles occurring in MWT and

* e-mail: atlas.publications@cern.ch
HVT models have been conducted by the ATLAS [20,21] and CMS [22] collaborations.

2 The ATLAS detector

The ATLAS detector [23] is a general-purpose particle detector used to investigate a broad range of physics processes. It includes inner tracking devices surrounded by a superconducting solenoid, electromagnetic and hadronic calorimeters and a muon spectrometer. The inner detector (ID) provides precision tracking of charged particles with pseudorapidity $|\eta| < 2.5$. The calorimeter system covers the pseudorapidity range $|\eta| < 4.9$. It is composed of sampling calorimeters with either liquid argon (LAr) or scintillator tiles as the active medium. The muon spectrometer consists of three large superconducting toroids and a system of trigger chambers and precision tracking chambers that provide triggering and tracking capabilities in the ranges of $|\eta| < 2.4$ and $|\eta| < 2.7$ respectively.

The ATLAS detector has a three-level trigger system to select events for offline analysis.

3 Data and Monte Carlo samples

This analysis is based on $\sqrt{s} = 8$ TeV pp collision data corresponding to $20.3 \pm 0.6$ fb$^{-1}$ [24]. The data used in the $\ell\nu\bar{b}b$ final state were collected using single-electron and single-muon triggers with transverse momentum ($p_T$) thresholds from 24 to 60 GeV. The data used in the $\ell\nu\bar{b}b$ final state were collected using a combination of single-electron, single-muon, dielectron ($ee$) and dimuon ($\mu\mu$) triggers. The $p_T$ thresholds for the $ee$ and $\mu\mu$ triggers vary from 12 to 13 GeV. The data used in the $\nu\nu\bar{b}b$ final state were collected using a trigger that requires a missing transverse momentum ($E_T^{\text{miss}}$) with magnitude $E_T^{\text{miss}} > 80$ GeV.

Simulated Monte Carlo (MC) samples for the MWT benchmark model use the implementation [25] in MADGRAPH5 [26], with the Higgs boson mass set to 126 GeV. The parameter $g$ is set to 2 for signal generation. Constraints on other values of this parameter can be set using the same samples since the kinematic distributions do not depend on $g$. The parameter $S$, which is an approximate value [27] of the Peskin–Takeuchi $S$ parameter [28] which measures potential new contributions to electroweak radiative corrections, is set to 0.3, in accordance with the recommendations in Ref. [29].

Signal samples for the HVT model are also generated with MADGRAPH5. The parameter $c_F$ is assumed to be the same for quarks and leptons including third-generation fermions. Other parameters involving more than one heavy vector boson, $gVVV, g_T^VcVV, g_T^VcVHH$ and $cVVW$, have negligible effect on the overall cross sections for the processes of interest here. For all signal events, parton showering and hadronization is performed with PYTHIA8 [30,31] and the CTEQ6L1 [32] parton distribution functions (PDFs) are used. Benchmark signal samples are generated for a range of resonance masses from 300 to 2000 GeV in steps of 100 GeV.

MC samples are used to model the shape and normalization of most SM background processes, although some are later adjusted using data-based corrections extracted from control samples. The production of $W$ and $Z$ bosons in association with jets is simulated with SHERPA 1.4.1 [33] using the CT10 PDFs [34]. Top quark pair production is simulated using POWHEG [35,36] with the POWHEG-BOX program [37] interfaced to PYTHIA6, using the CTEQ6L1 PDFs. In this analysis, the final normalizations of these dominant backgrounds are constrained by the data, but theoretical cross sections are used to optimize the selection. The cross sections are calculated at NNLO accuracy for $W/Z+$jets [38] and at NNLO+NNLL accuracy for $t\bar{t}$ [39]. Single top quark production is simulated with POWHEG and ACERMC [40] interfaced to PYTHIA6, using the CTEQ6L1 PDFs, and the cross sections are taken from Ref. [41]. Diboson production ($WW, WZ, ZZ$) is simulated using POWHEG interfaced to PYTHIA8, using the CT10 PDFs, and the cross sections are obtained at NLO from MCFM [42]. Finally, SM Higgs boson production in association with a $W/Z$ boson is simulated using PYTHIA8 with the CTEQ6L1 PDFs, and considered as a background in this search. It is scaled to the SM cross section [18].

All MC simulated samples include the effect of multiple pp interactions in the same and neighbouring bunch crossings (pile-up) by overlaying simulated minimum-bias events on each generated signal or background event. The number of overlaid events is such that the distribution of the number of interactions per pp bunch crossing in the simulation matches that observed in the data, with on average 21 interactions per bunch crossing. The generated samples are processed through the GEANT4-based ATLAS detector simulation [43,44] or a fast simulation using a parameterization of the performance of the calorimetry and GEANT4 for the other parts of the detector [45]. Simulated events are reconstructed with the standard ATLAS reconstruction software used for collision data.

4 Object reconstruction

The physics objects used in this analysis are electrons, muons, jets and missing transverse momentum.
Electrons are identified for $|\eta| < 2.47$ and $p_T > 7$ GeV from energy clusters in the electromagnetic calorimeter that are matched to tracks in the inner detector [46]. Quality requirements based on the calorimeter cluster and track are applied to reduce contamination from jets.

Muons are reconstructed in the muon spectrometer in the range $|\eta| < 2.7$ and $p_T > 4$ GeV [47]. For $|\eta| < 2.5$ the muon spectrometer track must be matched with a track in the inner detector and information from both is used to reconstruct the momentum. Muons considered for this analysis must have $p_T > 7$ GeV.

Lepton candidates are required to be isolated to reduce the multijet background. The scalar sum of the transverse momenta of tracks with $p_T > 1$ GeV within a cone of $\Delta R = \sqrt{(\Delta \eta)^2 + (\Delta \phi)^2} = 0.2$ around the lepton track (tracking isolation) is required to be less than 10% of the lepton $p_T$.

Jets are reconstructed using the anti-$k_t$ algorithm [48] with radius parameter $R = 0.4$. The jet transverse momentum is corrected for energy losses in passive material, for the non-compensating response of the calorimeter, and for any additional energy due to multiple $p p$ interactions [49]. Jets are required to have $p_T > 30$ GeV and $|\eta| < 4.5$. To reject low-$p_T$ jets from pile-up, for jets with $p_T < 50$ GeV and $|\eta| < 2.5$, the scalar sum of the $p_T$ of associated tracks, originating from the reconstructed primary vertex, is required to be at least 50% of the scalar sum of the $p_T$ of all associated tracks. To avoid double-counting of leptons and jets, an overlap removal procedure is applied [18].

In the pseudorapidity range $|\eta| < 2.5$, jets originating from $b$-quarks are identified using a multi-variate $b$-tagging algorithm [50]. This has an efficiency of 70% and a misidentification rate of less than 1% for selecting jets initiated by light quarks or gluons and of about 20% for jets initiated by $c$-quarks, as determined from $t\bar{t}$ MC events.

The missing transverse momentum is calculated as the negative of the vectorial sum of the calorimeter-based transverse momenta of all electrons, jets, and calibrated calorimeter clusters within $|\eta| < 4.9$ that are not associated with any other objects [51], as well as muon momenta. In addition, a track-based missing transverse momentum ($p_T^{\text{miss}}$), with magnitude $p_T^{\text{miss}}$, is used, calculated as the negative vectorial sum of the track-based transverse momenta of objects with $|\eta| < 2.4$ associated with the primary vertex.

5 Event selection and reconstruction

Events are categorized into the $\nu\nu b\bar{b}$, $\ell\nu b\bar{b}$ or $\ell\ell b\bar{b}$ channels if they have zero, one or two reconstructed charged leptons respectively. All categories require at least two jets in the pseudorapidity range $|\eta| < 2.5$ (central jets). The channels are further subdivided into categories of events containing one or two $b$-tagged jets; events with zero or $\geq 3$ $b$-tagged jets are rejected. The Higgs boson candidate (and its mass $m_{bb}$) is reconstructed from the two $b$-tagged jets or, for 1-$b$-tag events, the $b$-tagged jet and the highest-$p_T$ remaining central jet. In order to suppress $W/Z+jets$ background, at least one of the jets must have $p_T > 45$ GeV and the invariant mass of the dijet pair must be in the range $105 < m_{bb} < 145$ GeV, consistent with the Higgs mass. In order to reduce the $t\bar{t}$ background in the $\nu\nu b\bar{b}$ and $\ell\nu b\bar{b}$ channels, events are rejected if they contain four or more jets. To improve the resolution of the $VH$ mass a constraint to the Higgs boson mass is applied by scaling the Higgs boson candidate jet momenta by $m_H/m_{bb}$ ($m_H = 125$ GeV). Further channel-specific cuts are applied as outlined below.

5.1 $\nu\nu b\bar{b}$ channel

Events are selected with $E_T^{\text{miss}} > 120$ GeV and $p_T^{\text{miss}} > 30$ GeV. A requirement is made on $H_T$, defined as the scalar sum of the $p_T$ of all jets, in order to keep a high trigger efficiency: $H_T > 120$ GeV (>150 GeV) for events with two (three) jets. Selections are also applied on the angle between the jets used for reconstructing the Higgs candidate, $\Delta R_{bb}$, to suppress the $W/Z+jets$ background [18]: for $120 < E_T^{\text{miss}} < 160$ GeV, $0.7 < \Delta R_{bb} < 1.8$; for $160 < E_T^{\text{miss}} < 200$ GeV, $\Delta R_{bb} < 1.8$; for $E_T^{\text{miss}} > 200$ GeV, $\Delta R_{bb} < 1.4$. Events containing an electron or muon passing the selection cuts described in Sect. 4 are removed.

In events with real $E_T^{\text{miss}}$ the directions of $E_T^{\text{miss}}$ and $p_T^{\text{miss}}$ are expected to be similar. In events with fake $E_T^{\text{miss}}$ arising from a jet energy fluctuation, the direction of $E_T^{\text{miss}}$ should be close to the direction of the poorly measured jet. Therefore additional criteria are imposed on angular quantities in order to suppress the multijet background: the azimuthal angle between $E_T^{\text{miss}}$ and $p_T^{\text{miss}}$, $\Delta \phi(E_T^{\text{miss}}$, $p_T^{\text{miss}}) < \pi/2$; the minimum azimuthal angle between $E_T^{\text{miss}}$ and any jet, min($\Delta \phi(E_T^{\text{miss}}$, jet) > 1.5; and the azimuthal angle between $E_T^{\text{miss}}$ and the jet pair combination used to reconstruct the Higgs candidate, $\Delta \phi(E_T^{\text{miss}}$, $bb$) > 2.8.

It is not possible to accurately reconstruct the invariant mass of the $ZH$ system due to the missing neutrinos, so the transverse mass is used as the final discriminant:

$$m_T^{ZH} = \sqrt{(E_T^{bb} + E_T^{\text{miss}})^2 - (p_T^{bb} + E_T^{\text{miss}})^2},$$

where $p_T^{bb}$ is the transverse momentum of the Higgs candidate. The total acceptance times selection efficiency varies from 15% for $m_{R_1} = 400$ GeV, to 30% for $m_{R_1} = 1000$ GeV and down to 2% for $m_{R_1} = 2000$ GeV. The drop at very high masses is due to the merging of the jets.

5.2 $\ell\nu b\bar{b}$ channel

In order to suppress the multijet background and ensure the single-lepton triggers are fully efficient, tighter identification...
criteria are placed on the lepton in this channel. The lepton $p_T$ requirement is raised to $p_T > 25$ GeV and, for the muon channel, the pseudorapidity is restricted to $|\eta| < 2.5$. Moreover, the tracking isolation is tightened and required to be less than 4% of the lepton $p_T$. Similarly, the sum of transverse energy deposits in the calorimeter within a cone of $\Delta R = 0.3$ around the lepton, excluding the transverse energy due to the lepton and the correction for the expected pile-up contribution, is required to be less than 4% of the lepton $p_T$.

The multijet background is further reduced by requiring $\Delta\phi(E_{T\miss}^\ell, \text{jet}) > 1.0$. $W$ boson candidates are selected by requiring $E_{T\miss}^W > 30$ GeV and the transverse mass reconstructed from the lepton and $E_{T\miss}^W$, $m_W^T = \sqrt{2 \times E_T^\ell \times E_{T\miss}^W (1 - \cos\Delta\phi(\ell, E_{T\miss}^W))} > 20$ GeV.

The $W+H$ system mass, $m_{WH}$, is reconstructed from the lepton, the $E_{T\miss}^W$ and the two jets. The momentum of the neutrino in the $z$-direction, $p_z$, is obtained by imposing the $W$ boson mass constraint on the lepton and neutrino system, which leads to a quadratic equation. Here $p_z$ is taken as either the real component of the complex solutions or the smaller of the two real solutions.

In order to reduce the $W+\text{jets}$ background, a requirement is imposed on the transverse momentum of the $W$ boson, $p_T^W > 0.4 \times m_{WH}$. The cut depends on $m_{WH}$ since the background is generally produced at low $p_T^W$, whereas for signal the mean $p_T^W$ increases with $m_{WH}$. The total acceptance times selection efficiency varies from 8% for $m_{R_1} = 400$ GeV, to 20% for $m_{R_1} = 1000$ GeV and down to 2% for $m_{R_1} = 2000$ GeV.

### 5.3 $\ell\ell b\bar{b}$ channel

Events in this channel are selected by requiring two reconstructed leptons of the same flavour with opposite charge. In order to reduce the multijet background while keeping a high signal acceptance, tighter requirements are placed on one of the leptons. These tighter electrons or muons must have $p_T > 25$ GeV and, in addition, muons are restricted to $|\eta| < 2.5$. A cut on the two-lepton invariant mass of 83 GeV < $m_{\ell\ell}$ < 99 GeV is imposed to reduce $t\bar{t}$ and multijet backgrounds. The $t\bar{t}$ background is further reduced by requiring $E_{T\miss}^W < 60$ GeV.

The invariant mass of the two leptons and two jets is used to reconstruct $m_{WH}$.

In order to reduce the dominant $Z+\text{jets}$ background, a selection, optimized for this channel, is imposed on the transverse momentum of the $Z$ boson: $p_T^Z > 0.4 \times m_{WH} - 100$ GeV. The total acceptance times selection efficiency varies from 18% for $m_{R_1} = 400$ GeV, to 30% for $m_{R_1} = 1000$ GeV and down to 1% for $m_{R_1} = 2000$ GeV.

### 6 Background estimation

All backgrounds except the multijet background are estimated from simulation, with data-based corrections for the dominant $W/Z+\text{jets}$ background as described in the following. The rate and shape of the multijet (MJ) background are estimated with data-driven methods.

The MJ background is estimated in the 0-lepton channel using an “ABCD method” based on two uncorrelated variables: $\min|\Delta\phi(E_{T\miss}^\ell, \text{jet})|$ and $\Delta\phi(E_{T\miss}^\ell, p_T^\ell)$. The data are divided into four regions such that three of the regions are dominated by background. The signal region (A) is defined as explained in Sect. 5. The MJ-dominated region C is obtained by reversing the $\Delta\phi(E_{T\miss}^\ell, p_T^\ell)$ requirement. An MJ template in region A is obtained using events in region C after subtracting the contribution of other backgrounds, taken from simulation. The template is then normalized by a fit to the regions with $\min|\Delta\phi(E_{T\miss}^\ell, \text{jet})| < 0.4$ [18] (regions B and D with orthogonal $\Delta\phi(E_{T\miss}^\ell, p_T^\ell)$ requirements).

In the 1-lepton channel, the MJ background is determined separately for the electron and muon sub-channels. An MJ-background template is obtained from an MJ-dominated region after subtracting the small contribution from the other backgrounds. An MJ-dominated region is obtained by loosening the lepton identification requirements and reversing the isolation criteria. A binned fit of the full $E_{T\miss}^\ell$ spectrum of the data to the sum of the MJ contribution, $W/Z+\text{jets}$ and other MC contributions is then used to extract the MJ normalization. The templates are validated in a control region enriched in MJ events, selected by reversing the $E_{T\miss}^\ell$ requirement.

For the 2-lepton channel in the $eeb\bar{b}$ final state, the MJ background shape is determined by selecting events with reversed electron isolation criteria and its normalization is extracted by fitting the full data $m_{ee}$ distribution including $Z$ sidebands. The MJ background in the $\mu\mu b\bar{b}$ final state is found to be negligible.

The $W/Z+\text{jets}$ simulated samples are split into different components according to the true flavour of the jets, i.e. $W/Z+qq$, $W/Z+cq$, where $q$ denotes a light quark ($u$, $d$, $s$) or a gluon, and $W/Z$ plus heavy flavour (hf). The latter includes: $W/Z+b\bar{b}$, $W/Z+bg$, $W/Z+bc$, $W/Z+cc$. The normalizations of $W+cq$, $Z+cq$ and $W+hf$, $Z+hf$ are free parameters of the global likelihood fit. The scale factors after the fit are all consistent with 1, except for the $Z+hf$ normalization that is 15% higher as seen in previous measurements [18]. The $W/Z+\text{jets}$ modelling is checked in control regions selected by requiring events with no $b$-tagged jets or in the $m_{bb}$ sideband region in the 1-tag and 2-tag channels. A difference between data and simulation is observed in the 0-tag control region and a correction is extracted as a function of the azimuthal angle difference between the two leading-$p_T$ jets, $\Delta\phi(\text{jet}_1, \text{jet}_2)$. This is used to reweight the $Z+qq$ and $W+qq$ components. After this correction is
applied a discrepancy is observed in the $p_T^{T\ell}$ distribution
in the 2-lepton channel after the requirement of at least one
$b$-tagged jet. A correction is extracted and used to reweight
the $Z + cq$ and $Z + hf$ components. The full procedure is
described in detail in Ref. [18].

The background contributions from single top quark and
diboson production are normalized to the number of back-
ground events predicted by simulation while the $t\bar{t}$ normal-
ization is a free parameter in the likelihood fit. The descrip-
tion of the shape of the $t\bar{t}$ background from MC simulation
has been validated in samples dominated by top pair events.
Good agreement within uncertainties is observed between
data and expectation in these validation regions.

The $t\bar{t}$ control region is defined by requiring exactly one
electron and one muon, one of which has $p_T > 25$ GeV,
and two $b$-tagged jets. It is included in the likelihood fit to
constrain the $t\bar{t}$ normalization. The scale factor for the $t\bar{t}$
normalization is found to be $1.03 \pm 0.04$ after the likelihood
fit to the 0- and 2-lepton channel plus the $t\bar{t}$ control region,
and $0.99 \pm 0.09$ from the fit to the 1-lepton channel. The fit
procedure is described in more detail in Sect. 8.

7 Systematic uncertainties

The most important experimental systematic uncertainties
come from the jet energy scale (JES) and $b$-tagging effi-
ciency.

The JES systematic uncertainty arises from several sources
including uncertainties from the in-situ calibration, the cor-
rections dependent on pile-up and the jet flavour composi-
tion [52]. The fractional systematic uncertainty on the JES
ranges from $3\%$ for a $20$ GeV jet to $1\%$ for a $1$ TeV jet.

The uncertainty due to the jet energy resolution is also
considered. It varies from $20\%$ for a jet with $p_T > 20$ GeV
to $5\%$ for a jet with $p_T > 1$ TeV. The jet energy scale
and resolution uncertainties are propagated to the reconstructed
$E_{T}^{miss}$. The uncertainty on $E_{T}^{miss}$ also has a contribution from
hadronic energy that is not included in jets [53].

The $b$-tagging efficiency uncertainty depends on jet $p_T$
and comes mainly from the uncertainty on the measurement
of the efficiency in $t\bar{t}$ events [50]. Uncertainties are also
derived for $c$- and light-flavour jet tagging [54].

Other experimental systematic uncertainties that have a
smaller impact are those on the lepton energy scale and iden-
tification efficiency and the efficiency of the triggers.

In addition to the experimental systematic uncertainties,
uncertainties are taken into account for possible differences
between data and the simulation model that is used for each
process. For the background modelling uncertainties the pro-
cedure described in Ref. [18] is followed. The $Z+j$-jets and
$W+j$-jets backgrounds include uncertainties on the relative
fraction of the different flavour components, and shape uncer-
tainties on the modelling of $m_{h\bar{h}}$, $\Delta\phi(j_{1},j_{2})$ and $p_{T}^{Z}$ dis-
tributions. For $t\bar{t}$ production, shape uncertainties are included
for the modelling of top quark transverse momentum, $m_{h\bar{h}}$
and $m_{VH}$ distributions. The uncertainty on the MJ back-
ground shape in the 1-lepton channel is evaluated by using
alternative templates obtained by changing the definition of
the data sidebands. The uncertainty on the MJ background
normalization is taken to be $100$, $30$ and $50\%$ for the $0$-, $1$-
and $2$-lepton channels, respectively. These are extracted from
fits using alternative templates.

The dominant uncertainties on the signal acceptance arise
from the choice of PDFs ($2-5\%$) estimated by comparing
the default PDFs to other sets, and from the factorization and
renormalization scales ($5-10\%$) obtained by varying these
up and down by a factor of two.

8 Results and limit extraction

The reconstructed mass distributions for events passing the
selection are shown in Fig. 1. The background expectation
is shown after the profile likelihood fit to the data. Table 1
shows the number of events expected and observed in each
final state.

No significant excess of events is observed in the data
compared to the prediction from SM background sources.
Exclusion limits at the $95\%$ confidence level (CL) are set
on the production cross section times the branching frac-
tion for MWT and HVT models. The limits for the charged
resonance are obtained by performing the likelihood fit over
the $\ell\nu b\bar{b}$ channel alone, while the $\ell\ell b\bar{b}$, $\nu\nu b\bar{b}$ channels
as well as the $t\bar{t}$ control region are used for the neutral
resonance.

The exclusion limits are calculated with a modified fre-
quentist method [55], also known as $CL_s$, and the profile-
likelihood test statistic [56], using the binned $m_{VH}$ mass dis-
tributions for $\ell\nu b\bar{b}$, $\ell\ell b\bar{b}$ and $\nu\nu b\bar{b}$ final states. Systematic
uncertainties and their correlations are taken into account
as nuisance parameters. None of the systematic uncertain-
ties considered are significantly constrained or pulled in the
likelihood fit. Figure 2 shows $95\%$ CL upper limits on the
production cross section multiplied by the branching frac-
tion into $WH$ and $ZH$ as a function of the resonance mass
separately for the charged $R_{T}^{T}\ell$ and for the neutral $R_{T}^{0}$
limits. The experimental limits are obtained using samples with a sin-
gle resonance $R_{1}$, where the cross section for $R_{2}$ has been
set to zero to be less model-dependent. The theoretical pre-
dictions for the HVT benchmark model $A$ with coupling
constant $g_{V} = 1$ allow exclusion of $m_{VH} < 1360$ GeV
$(m_{VH} < 1470$ GeV). For the MWT model, since there are
two resonances of different mass, the results are displayed for
the first one, $R_{1}^{0,\pm}$. The excluded regions are $m_{R_{1}} < 410$ GeV,
Fig. 1 Distributions of the reconstructed, a transverse mass $m_{T \nu \nu}$ for the $\nu \nu$ final state, b invariant mass $m_{\ell \nu}$ for the $\ell \nu \bar{b} \bar{b}$ final state and c invariant mass $m_{\ell \ell}$ for the $\ell \ell \bar{b} \bar{b}$ final state for the 1-b-tag (upper) and 2-b-tag (lower) channels. The background expectation is shown after the profile likelihood fit to the data. Any overflow is included in the last bin. The signals are shown stacked on top of the background and correspond to the benchmark models MWT with $m_{R_1} = 700$ GeV and HVT with $m_{V'} = 1000$ GeV normalized to the expected cross sections.

Table 1 The number of expected and observed events for the three final states. The expectation is shown after the profile likelihood fit to the data. The quoted uncertainties are the combined systematic and statistical uncertainties. The overall background is more constrained than the individual components, causing the errors of individual components to be anti-correlated.

The exclusion contours in the HVT parameter space $\{(g^2/g_V)c_F, g_V c_H\}$ for resonances of mass 1, 1.5 and 1.8 TeV are shown in Fig. 4 where all three channels are combined, taking into account the branching ratios to $WH$ and $ZH$ from the HVT model. These contours are produced by scanning the parameter space, using the HVT tools provided in a web-interface [15, 57].
Fig. 2 Combined upper limits at the 95% CL for 
\( a \) the production cross section of \( R_0(V^0) \) times its branching ratio to \( ZH \) and branching ratio of \( H \) to \( bb \) and \( b \) the production cross section of \( R_{\pm}(V^{\pm}) \) times its branching ratio to \( WH \) and branching ratio of \( H \) to \( bb \). The experimental limits are obtained using samples with a single resonance \( R_1 \); however, the theory curve line for MWT includes both \( R_1 \) and \( R_2 \). The dip near 500 GeV in this theory curve is due to the interference between \( R_1 \) and \( R_2 \) [7].

Fig. 3 Exclusion contours at 95% CL in the plane of the Minimal Walking Technicolor parameter space defined by the bare axial-vector mass versus the strength of the spin-1 resonance interaction \( (m_{A, \tilde{g}}) \). Electroweak precision measurements exclude the (green) area in the bottom left corner. The requirement to stay in the walking regime excludes the (blue) area in the right corner. The large (red) area (black dashed line) shows the observed (expected) exclusion. The blue dashed line shows the observed exclusion from the dilepton resonance search [21]. The upper region is excluded due to non-real axial and axial-vector decay constants. Here both resonances predicted by MWT, \( R_1 \) and \( R_2 \), are fitted simultaneously.

9 Summary

A search for a new heavy resonance decaying to \( WH / ZH \) is presented in this Letter. The search is performed using 20.3 fb\(^{-1} \) of \( pp \) collision data at 8 TeV centre-of-mass energy collected by the ATLAS detector at the Large Hadron Collider. No significant deviations from the SM background predictions are observed in the three final states considered: \( \ell\ell bb \), \( \ell\nu bb \), and \( \nu\nu bb \). Upper limits are set at the 95% confidence level on the production cross sections of \( R_1 \) and \( V' \) for the Minimal Walking Technicolor and Heavy Vector Triplets models respectively. Exclusion contours at 95% CL in the MWT parameter space \( \{m_A, \tilde{g}\} \) and in the HVT parameter space \( \{(g^2/g_V)c_F, g_Vc_H\} \) are presented.

Acknowledgments We thank CERN for the very successful operation of the LHC, as well as the support staff from our institutions without whom ATLAS could not be operated efficiently.
