Unstimulated Peripheral Blood Mononuclear Cells from Patients with the Hyper-IgD Syndrome Produce Cytokines Capable of Potent Induction of C-Reactive Protein and Serum Amyloid A in Hep3B Cells

Joost P. H. Drenth,1**, Jos W. M. Van Der Meer,2+ and Irving Kushner*

The hyper-IgD and periodic fever syndrome (HIDS)1 is a rare disease characterized by recurrent febrile attacks with abdominal complaints, lymphadenopathy, skin lesions, and joint involvement. Up to now, some 65 patients, mainly of European origin, have been recognized (1). A clinically similar entity, familial Mediterranean fever (FMF), is an autosomal recessive inflammatory disorder characterized by short episodes of fever, peritonitis, pleuritis, and arthritis (2), which predominantly affects non-Ashkenazi Jews, Armenians, and Arabs. The pathogenesis of these periodic fever syndromes is unknown, but it is probable that attacks arise from dysregulation of the inflammatory response in both. For example, a lack of CsA inhibitor has been incriminated as a cause of the recurrent attacks of serositis in FMF (3).

3 Abbreviations used in this paper: HIDS, hyper-IgD periodic fever syndrome; FMF, familial Mediterranean fever; CM, conditioned medium; CRP, C-reactive protein; SAA, serum amyloid A; AGP, α1-acid glycoprotein; HIDS-CM, conditioned medium prepared from peripheral blood mononuclear cells derived from patients with familial Mediterranean fever; C-CM, conditioned medium prepared from peripheral blood mononuclear cells derived from control adults; HIDS-CM, conditioned medium prepared from peripheral blood mononuclear cells derived from patients with hyper-IgD syndrome; TBS, Tris-buffered saline; OPD, o-phenylenediamine.

Materials and Methods

Patients

Eight patients with HIDS (four male, mean age: 25.9 yr); six patients with FMF (three male, mean age: 25.3 yr), and seven healthy Dutch volunteers (seven males, mean age: 30.3 yr) took part in the study. The diagnoses of HIDS and FMF were made according to standard criteria listed elsewhere.
Peripheral blood was drawn into sterile 10-ml tubes containing 0.2 mg EDTA. PBMC were isolated by buoyant density gradient centrifugation on Percol (12). The cells from the interphase were aspirated and washed twice with sterile saline. After the last washing, cells were resuspended at a concentration of 5 × 10^6/ml in RPMI 1640 medium (Dutch modification; Flow Labs, Irvine, Scotland) supplemented with 2 mM L-glutamine, 1 mM pyruvate, and 500 μg/ml gentamicin. Medium was loaded onto a 50-ml syringe and forced through a 0.2-μm filter by manual force to remove endotoxin and other cytokine-inducing material (13). Heat-inactivated (30 min at 56°C) pooled human sera (5%) was added after filtration. PBMC were resuspended at a concentration of 5 × 10^6/ml in round-bottom 96-well plastic tissue culture plates and incubated either with or without 100 ng/ml lipopolysaccharide (LPS) at 37°C in a humidified atmosphere containing 5% CO₂ for 24 h. Fifty microliters of the PBMC suspension was applied to cytosin centrifugation, and the contribution of monocytes to the PBMC solution was assessed microscopically under high powered view. The contribution of monocytes to the PBMC solution was similar for each group (HIDS, 17.5 ± 5.8%; FMF, 16 ± 6%; controls, 18 ± 6.8%). After incubation, the culture plates were centrifuged at 4000 × g for 10 min to remove cellular material. Cell supernatants (CM) were then aspirated and stored at −70°C for baseline value measurement. CRP in the CM of the patients and controls. This baseline value was subtracted from the total amount of CRP subsequently released into the medium by Hep3B cells to calculate actual CRP production.

**Cultures of Hep3B cells**

Human hepatoma cells, Hep3B, were maintained in RPMI 1640 medium supplemented with 10% fetal bovine serum. Cells were subcultured weekly after trypsinization. Induction of acute phase proteins was conducted when cells were confluent, usually on day 6 after subculture. Hep3B cells were incubated at 37°C in 5% CO₂ for 18 h. The medium was collected after 24 h and stored at −70°C until analysis. ELISAs

**Cytokine production by PBMC**

Total RNA was isolated from stimulated Hep3B cells by guanidinium isothiocyanate lysis following a modification of the method of Chomczynski and Sacchi (16). RNA samples (15 μg per lane) were heat denatured at 65°C in a solution consisting of 50% deionized formamide, 2 M formaldehyde in 0.2 M 3-(N-morpholino)propanesulfonic acid buffer, pH 7.0, with 10 mM EDTA, and then fractionated on 1% agarose gels containing 2.2 M formaldehyde. After transfer to Magnagraph nylon (Micron Separations Inc., Westboro, MA) by 3 h of vacuum blotting, RNA was UV cross-linked to the membrane. Dried membranes were photographed under UV transillumination. Prehybridization (4 h) and hybridization (18 h) with CRP and SAA cDNA probes labeled with [32P]dCTP by the random primer method (10⁶ cpm) were performed at 42°C in hybridization buffer containing 50% deionized formamide, 5× standard saline solution (SSC), 1× Denhardt’s solution, 1% SDS, and 10 μg/ml denatured salmon sperm DNA. Following hybridization, nonspecifically bound radioactivity was removed from membranes by washing twice with 6× SSC, 0.1% SDS at room temperature, then washed 30 min followed by two subsequent washes for 15 min with 0.1× SSC, 0.1% SDS at 62°C. The membranes were then exposed at −70°C to X-OMAT AR Kodak film. Membranes were stripped with 5 min of exposure to 95°C distilled H₂O containing 1% SDS before hybridization with the next labeled probe. The probes used were: 1) CRP, pCRP5, kindly provided by H. R. Colten, Washington University, St. Louis, MO (17); and 2) SAA, pa10 (capable of detecting all SAA isoforms) courtesy of J. Sipe, Boston University, Boston, MA (18). The intensities of 18S RNA bands on photographs of ethidium bromide-stained formaldehyde gels and of mRNA bands on autoradiographs were measured by using a UMAGE scanner (Data System Inc., Hsinchu, Taiwan) with the software Intelligent Quencher for Macintosh (Bio Image, Ann Arbor, MI). Densitometry of 18S rRNA bands was used to correct for minor technical variations and the autoradiograph band intensities were adjusted appropriately.

**Statistical analysis**

All results are shown as the mean ± SEM. Comparison between groups was assessed by the unpaired nonparametric Mann Whitney U test. A p value of <0.05 was considered to be the lowest level of significance.

**Results**

**Serum concentrations of acute phase proteins**

The CRP content in serum drawn from the patients was higher compared with the healthy control group, albeit the difference was not statistically significant (Table I). Serum from HIDS patients and FMF patients contained comparable quantities of SAA but the concentrations were (nonsignificantly) higher compared with the control group.

**Cytokine production by PBMC**

The concentrations of cytokines in CM, reflecting production by PBMC over 24 h of incubation, are indicated in Table II. CM derived from unstimulated PBMC from HIDS patients (HIDS-CM) contained significantly more IL-1β, IL-6, and TNF-α than

did CM derived from PBMC of FMF patients (FMF-CM). FMF-CM, in turn, contained significantly more IL-1β and IL-6, but not TNF-α, than did CM derived from PBMC of healthy controls (C-CM). In all three groups, cytokine production by PBMC stimulated with 100 ng/ml LPS was significantly increased compared with unstimulated PBMCs (Table I). Stimulated HIDS-CM contained threefold more IL-1β and twofold more IL-6 than did stimulated FMF-CM. Unlike unstimulated PBMC, LPS-stimulated PBMC derived from HIDS and FMF patients produced comparable amounts of TNF-α. LPS-stimulated FMF-CM contained more IL-1β than did C-CM, while IL-1 and TNF-α production did not differ between these two groups.

Acute-phase response to CM

Unstimulated PBMC. Incubation of Hep3B cells for 24 h with unstimulated HIDS-CM resulted in fivefold greater accumulation of CRP in culture medium, reflecting greater production, than was observed with unstimulated FMF-CM (p < 0.001) or C-CM (p < 0.005) (Fig. 1). Unstimulated HIDS-CM also caused significantly greater increases in levels of mRNA in Hep3B cells for CRP (sevenfold) and SAA (50-fold) than did unstimulated FMF-CM (Fig. 2, A and B). Unstimulated HIDS-CM induced about 2.6-fold higher CRP mRNA and fivefold higher mRNA levels for SAA than did C-CM but neither of these differences could be shown to achieve statistical significance.

LPS-stimulated PBMC. For all three groups, stimulation with LPS led to production of CM capable of greater acute phase protein-inducing ability than was seen with unstimulated PBMC. Hep3B cells incubated with stimulated HIDS-CM secreted fivefold more CRP than did cells incubated with stimulated FMF-CM or C-CM (Fig. 3), and 2.4-fold more than cells incubated with unstimulated HIDS-CM (p = 0.009). Following incubation of Hep 3B cells with LPS-stimulated HIDS-CM, CRP and SAA mRNA levels were significantly greater than was observed following incubation with FMF-CM or C-CM (Fig. 2, C and D). Serum SAA and CRP concentrations (determined during disease inactivity) did not correlate with acute phase protein-inducing activity of both the stimulated and unstimulated samples we tested.

Discussion

The major purpose of the current investigation was to determine the extent to which clinically observed differences in the magnitude of the acute phase response in HIDS and FMF patients, as measured by serum levels of acute phase proteins, could be attributed to differences in release of inflammatory cytokines by PBMC from these patients (Refs. 6–8; and J. P. H. Drenth, personal observations). We found that unstimulated PBMC from patients with inactive HIDS released significantly more IL-1β, IL-6, and TNF-α than did PBMC from patients with FMF, and that CM from these cells induced significantly greater CRP production and significantly more mRNA for CRP and SAA in Hep3B cells than did CM from FMF patients. These results support the hypothesis that differences in the magnitude of the acute phase response between HIDS and FMF patients reflect differences in cytokine production by their PBMC and indicate that these effects on acute phase protein production are exerted at the pretranslational level. We studied PBMC rather than monocytes because isolation of monocytes involves an adherence step that may itself activate these cells, which we wanted to avoid. To the extent to which findings in PBMC reflect the behavior of monocytes and tissue macrophages, our findings raise the possibility that macrophages may also produce large amounts of these inflammatory cytokines in patients with HIDS. The results from our study cannot be explained by differences in monocyte content in the PBMC since this was similar for all studied groups.

Serum SAA and CRP concentrations (determined during disease inactivity) were relatively low in both patient groups, although greater than those seen in controls, and did not correlate with acute phase protein-inducing activity of the samples we tested. This came as no surprise, since in vivo and in vitro circumstances are quite different. Our in vitro assay is relatively insensitive, based on protracted exposure of Hepatoma cells to an unchanging test sample, while in vivo acute phase protein levels reflect effects of continuous flow of plasma on in situ hepatocytes and of clearance of acute phase proteins from plasma.

In addition, our findings also indicate that PBMC are already markedly activated in vivo in patients with inactive HIDS. In contrast, unstimulated PBMC from patients with inactive FMF produced substantially less IL-1β and IL-6, and their TNF-α production was indistinguishable from that seen in PBMC from healthy controls. Overproduction of cytokines by unstimulated PBMC from HIDS patients could be due either to faulty regulation of autonomous cytokine production or to the effects of an exogenous stimulatory factor. Recent findings favor the latter explanation: IgD isolated from HIDS patients has been found to stimulate normal human PBMC to produce large quantities of IL-1β, IL-6, TNF-α, and leukocyte inhibitory factor. (19). It is reasonable to conclude, in light of our current findings, that the high concentrations of IgD seen in these patients serve as a continuous stimulus to inflammatory cytokine production, even during clinically inactive periods. This conclusion is consistent with our previous observation that increased fucosylation of AGP, a phenomenon shown to be due to the effects of cytokines (20), is found in patients during asymptomatic intervals. The finding that CM derived from unstimulated PBMC from HIDS patients in the intercritical phase is able to induce an acute phase response in Hep3B cells, a relatively insensitive bioassay (21), supports this conclusion, as does the observation that serum AGP concentrations are persistently elevated between attacks and increase slightly during febrile attacks of HIDS (20).

There has been similar interest in the effect of CM derived from circulating cells on the synthesis of acute phase proteins in other inflammatory disorders. Patients with active Crohn’s disease generally have higher circulating CRP concentrations compared with those with ulcerative colitis (22). IL-1β and TNF-α production by unstimulated peripheral monocytes was not different in cells from patients with Crohn’s disease than in those with ulcerative colitis, but LPS-stimulated cytokine production was significantly higher in monocytes from Crohn’s disease patients (22) and this difference was even greater during active disease. CM from both unstimulated and stimulated monocytes from patients with active Crohn’s disease induced greater release of CRP from PLC/PRF/5 human hepatoma cells than did CM from patients with active ulcerative colitis (23). Similarly, CM from unstimulated and LPS-stimulated
The journal of Immunology 403

The differences we observed in the profile of cytokines produced by unstimulated PBMC from patients with inactive HIDS and FMF patients differed in their capacity to elicit CRP production and acute phase protein mRNA changes in Hep3B cells, these findings suggest differences in the pathogenesis of these two intermittent febrile disorders.

Finally, the observation that HIDS PBMC, although already activated, were able to respond to LPS stimulation with further increase in cytokine production and increased acute phase protein-inducing capability is consistent with the hypothesis that acute febrile attacks are precipitated by unknown stimuli capable of further increasing cytokine production. There is evidence that the ability to produce cytokines in HIDS patients increases during febrile attacks. In these patients, LPS-stimulated ex vivo production of TNF-α and IL-1β, as measured in a whole blood culture system, was found to be significantly greater during acute attacks than following defervescence (6). In contrast, LPS-stimulated TNF-α and IL-1β production in supernatants of PBMC from FMF patients was markedly decreased during febrile attacks but normalized during recovery (25–27). This apparent differential regulation of cytokines during attacks in these two syndromes might further explain the difference in the magnitude of the acute phase response observed in vivo.
