Received 10 March 1996 and accepted 18 March 1996

Summary

Indium-111 (\textsuperscript{111}In) and technetium-99m (\textsuperscript{99mTc}) Stealth\textsuperscript{R} liposomes were compared with \textsuperscript{111}In- and \textsuperscript{99mTc}-labelled white blood cells (WBC) in experimental infection in a rabbit model. Preformed polyethylene glycol-coated liposomes and separated WBC were radiolabelled with either \textsuperscript{111}In-oxine or \textsuperscript{99mTc}-hexamethylpropyleneamine oxime (\textsuperscript{99mTc}-HMPAO). After the intravenous administration of one of the four radiopharmaceuticals to rabbits with focal \textit{Staphylococcus aureus} infection, scintigraphic images were recorded at various time points post-injection and the biodistribution of the radiopharmaceuticals was determined. At 4 h post-injection, uptake of \textsuperscript{111}In-WBC in the abscess was significantly higher than that of the three other products. At later time points, \textsuperscript{111}In-WBC, \textsuperscript{111}In-liposome and \textsuperscript{99mTc}-liposome uptake in the abscess were similar. In contrast, at 20 h post-injection, uptake of \textsuperscript{99mTc}-WBC was significantly lower. The abscess-to-background ratios showed a similar pattern to the absolute abscess uptake: initial high values for \textsuperscript{111}In-WBC, a more gradual increase over time of the liposome preparations to the level of \textsuperscript{111}In-WBC and persistently low values for \textsuperscript{99mTc}-WBC. Clearance from the blood of both labelled WBC preparations was significantly faster and splenic uptake significantly higher compared with those of the labelled liposomes. In conclusion, given the similar \textit{in vivo} characteristics of labelled liposomes and labelled WBC, labelled liposomes may be an attractive replacement for labelled WBC, providing a continuously available, high-quality, \textsuperscript{99mTc}-labelled radiopharmaceutical that can be prepared easily without any need to handle blood.

Introduction

Scintigraphic delineation of focal infection is a clinically important procedure, not only to identify infectious and inflammatory foci, but also to evaluate their activity [1]. Despite the development of new agents, autologous leukocyte (WBC) scintigraphy, using either indium-111 (\textsuperscript{111}In) or technetium-99m (\textsuperscript{99mTc}), is still the imaging procedure of choice in routine clinical practice [2]. Unfortunately, the preparation of radiolabelled autologous leukocytes has several disadvantages which limit its application. In particular, the need to withdraw and handle blood that may be infected constitutes an inherent risk to other patients and staff [3, 4]. Moreover, the isolation and labelling of leukocytes is a relatively complicated and time-consuming procedure that is not possible in every laboratory. One approach to facilitate infection imaging is the application of labelled proteins and peptides [5–7]. These radiopharmaceuticals accumulate in infection by specific receptor or antigen interaction or non-specific deposition [7]. Another method to prevent the handling of blood is the use of Stealth\textsuperscript{R} liposomes. These are phospholipid bilayers with a polyethylene coating that prevent rapid uptake of circulating particles by the mononuclear phagocytic system [8].
These liposomes are radiolabelled analogously to leukocytes either with $^{111}$In or $^{99m}$Tc$^m$ [9, 10]. In initial animal studies, a number of characteristics of labelled liposomes resembled those of labelled leukocytes in humans in terms of biodistribution and the ability to detect various infections [10]. In this study, the $in\text{ vivo}$ characteristics of labelled StealthR liposomes are compared with those of labelled leukocytes, both labelled with either $^{111}$In or $^{99m}$Tc$^m$ in a rabbit model of mild focal Staphylococcus aureus infection.

Materials and methods

Animal model

A calf muscle abscess was induced in female, randomly bred New Zealand white rabbits (body weight 2.5-3.0 kg). Approximately $10^9$ colony forming units (CFU) of S. aureus in 0.5 ml of a 50:50% suspension of autologous blood and normal saline was injected into the left calf muscle [11]. Twenty-four hours after the inoculation, when swelling of the muscle was apparent, the respective radiopharmaceuticals were injected via the ear vein.

Preparation of liposomes

Partially hydrogenated egg-phosphatidylcholine with an iodine value of 40 (PHEPC) was obtained from Asahi Chemical Industry Co., Ltd (Ibarakiken, Japan) [12]. The polyethylene glycol (PEG) 1900 derivative of distearoylphosphatidyl-ethanolamine (PEG-DSPE) was a kind gift from Liposome Technology, Inc. (Menlo Park, CA) and prepared as described previously [13]. The cholesterol was obtained from Sigma Chemical Co. (St. Louis, MO) and the glutathione from E. Merck (Darmstadt, Germany). A chloroform/methanol mixture (10/1, v/v) containing PEG-DSPE, PHEPC and cholesterol was prepared in a molar ratio of 0.15:1.85:1. A lipid film was formed by rotary evaporation followed by high vacuum to remove residual organic solvent [14].

For encapsulation of glutathione (for subsequent $^{99m}$Tc$^m$ labelling), the film was hydrated at room temperature with 50 mM glutathione in HEPES buffer (10 mM HEPES, 135 mM NaCl, pH 7.4) at an initial phospholipid concentration of 120 mM. For encapsulation of Desferal (for subsequent $^{111}$In labelling), the lipids were dispersed at room temperature in 6 mM Desferal in 0.9% HEPES buffer (10 mM HEPES, 135 mM NaCl, pH 7.5) at an initial phospholipid concentration of 120 mM. The liposomes were sequentially extruded through polycarbonate filters of 0.6, 0.2, 0.1 and 0.08 μm pore size (Poretics, Livermore, CA, USA). Unentrapped glutathione or Desferal was removed by gel filtration on an EconoPac 10DG column (Bio-Rad, Richmond, CA, USA). The particle size distribution was determined by dynamic light scattering with a Malvern 4700 system using a 25 mW He-Ne laser and the automeasure 3.2 software (Malvern, UK). As a measure of particle size distribution of the dispersion, a polydispersity index was determined, ranging from 0.0 (entirely monodisperse) to 1.0 (completely polydisperse). The mean size of the liposome dispersions was 120 nm, with a polydispersity index of 0.2.

Radiolabelling of liposomes

Preformed glutathione-containing liposomes were labelled by transporting $^{99m}$Tc$^m$ as a lipophilic $^{99m}$Tc$^m$-hexamethylpropyleneamine oxime ($^{99m}$Tc$^m$-HMPAO) complex through the bilayer. The $^{99m}$Tc$^m$-HMPAO in a rabbit model of mild focal Staphylococcus aureus infection.

Preparation and radiolabelling of leukocytes

For each labelling, 100 ml of blood was withdrawn carefully from an anaesthetized donor rabbit by carotid artery cannulation into 60 ml syringes, each containing 10 ml 0.33% methylcellulose in acid citrate dextrose (ACD). The total white blood cell count of the donor rabbits was $8.5 \times 10^9$ I$^{-1}$ ($^{99m}$Tc$^m$ labelling) and $12 \times 10^9$ I$^{-1}$ ($^{111}$In labelling) with approximately 50% granulocytes. The erythrocytes were allowed to sediment for 1 h. The supernatant was removed and centrifuged for 10 min at 450 g. The cell pellet was washed with 5 ml phosphate buffered saline (PBS) (pH = 7.4). 1% HSA and centrifuged once more for 10 min at 450 g. The cell pellet was resuspended in 1.5 ml in PBS, 1% HSA. Then, 2 GBq
99mTc-HMPAO or 100 MBq 111In-oxine solution (Mallinckrodt Medical, Petten, The Netherlands) in 0.2 M Tris-hydroxymethyl-aminomethane (pH = 8.0) was added to the cell suspension. The cells were incubated at room temperature for 30 min and centrifuged for 10 min at 450 g. The cell pellet was resuspended in 5 ml PBS, 1% HSA (111In-WBC) or 5% glucose (99mTc-WBC). Morphological integrity of the WBC was checked by light microscopy examination. The labelling efficiency (cell associated activity/total activity) was higher than 95% for 111In-WBC and 75% for 99mTc-WBC. Twenty MBq 111In-WBC or 200 MBq 99mTc-WBC were administered intravenously.

**Study design**

Twenty-four hours after *S. aureus* infection, groups of four rabbits each were injected via the ear vein with either 99mTc-liposomes, 99mTc-WBC, 111In-liposomes or 111In-WBC. The rabbits were immobilized and placed prone on a single-head gamma camera equipped with a parallel-hole, low-energy (99mTc studies) or medium-energy (111In studies) collimator (Siemens Orbiter, Siemens Inc., Hoffmann Estate, IL). Each rabbit was imaged at 5 min, 1 h, 4 h, 8 h, 20 h and 48 h (111In only) after injection. Images (100,000 counts per rabbit) were obtained and stored in a 256 x 256 matrix.

The scintigrams were analysed by drawing regions of interest over the abscess, over the non-infected contralateral calf muscle (used as a background region), over the heart (representing blood pool activity), the lung (labelled leukocytes) and over the whole animal. Whole-body retention, blood clearance, lung clearance, abscess-to-background ratios and percentage activity remaining in the abscess (abscess-to-whole body ratio) were calculated.

After acquiring the final images, the rabbits were sacrificed with an overdose of sodium phenobarbital and biodistribution was determined. Blood was obtained by cardiac puncture. Tissues (infected left calf muscle, right calf muscle, liver, spleen, kidney, duodenum, right femur and bone marrow from the right femur) were dissected, weighed and their activity was measured in a shielded well-type gamma counter. To correct for physical decay and to permit calculation of the uptake of the radiopharmaceuticals in each organ as a fraction of the injected dose, aliquots of the injected dose were counted simultaneously. The results were expressed as

---

**Fig. 1.** (A) 111In-WBC and (B) 111In-liposomes 48 h post-injection; (C) 99mTc-WBC and (D) 99mTc-liposomes 20 h post-injection. In all images, the *S. aureus* abscess can be clearly seen (arrow). For all four radiopharmaceuticals, spleen (WBC > liposomes), liver and bone marrow uptake can be visualized. The 99mTc-labelled preparations show renal uptake and both liposome products residual blood pool activity (heart). Gut activity is only apparent after injection of 99mTc-WBC.
percent injected dose per gram (%ID g^{-1}). Abscess-to-muscle, abscess-to-blood and abscess-to-bone marrow ratios were calculated.

**Statistical analysis**

All mean values are given as %ID g^{-1} or ratios ± one standard error of the mean (s.e.m.). Statistical analysis was performed using one-way analysis of variance (ANOVA). The level of significance was set at \( P < 0.05 \).

**Results**

Figure 1 shows images recorded at 48 h (\( ^{111}\text{In} \) label) and 20 h (\( ^{99}\text{Tc} \) label) post-injection. The abscess can be clearly seen with all four radiopharmaceuticals. Quantitative analysis of the scintigraphic data revealed very similar whole-body retention over time of \( ^{111}\text{In}-\text{WBC} \) and \( ^{111}\text{In}-\text{liposomes} \) (Fig. 2A). The \( ^{99}\text{Tc} \) preparations cleared significantly faster from the body than the \( ^{111}\text{In}-\text{liposomes} \) (after 1 h post-injection, \( P < 0.05 \)).

From 8 h post-injection onwards, the whole-body retention of \( ^{99}\text{Tc} \)-WBC was significantly lower than that of \( ^{99}\text{Tc} \)-liposomes. In contrast, blood clearance of both liposome formulations was significantly slower than the blood clearance of labelled WBC (\( P < 0.001 \) at 1 h post-injection and all later time points; see Fig. 2B). There was no difference between \( ^{111}\text{In} \)- and \( ^{99}\text{Tc} \)-liposome blood clearance, nor between \( ^{111}\text{In} \)- and \( ^{99}\text{Tc} \)-WBC blood clearance. While both liposome formulations showed low pulmonary activity, both \( ^{111}\text{In} \)- and \( ^{99}\text{Tc} \)-labelled WBC showed initial margination in the lungs (image not shown). As shown in Fig. 2C, after the initial entrapment in the lungs, fast clearance of the labelled cells from the lungs into the circulation was observed with a first half-life of less than 1 h. From 4 h post-injection onwards, the relative pulmonary uptake of \( ^{99}\text{Tc} \)-WBC was significantly lower than that of \( ^{111}\text{In}-\text{WBC} \) (\( P < 0.05 \)).

Figure 3A shows abscess uptake over time as determined scintigraphically. At 4 h post-injection, uptake of \( ^{111}\text{In}-\text{WBC} \) was significantly higher than that of the other three radiopharmaceuticals (\( P < 0.05 \)). At later time
points, uptake of $^{111}$In-WBC, $^{111}$In-liposome and $^{99}$Tc-m.-
liposome in the abscess was similar. In contrast, at 20 h
post-injection, uptake of $^{99}$Tc-m.-WBC was significantly
lower than the uptake of the other three radiopharma­
aceuticals ($P < 0.05$). The abscess-to-background ratios
(Fig. 3B) and the remaining activity in the abscess (Fig.
3C) showed a similar pattern to the absolute abscess
uptake: initial high values for $^{111}$In-WBC, a more gradual
increase over time of the liposome preparations to the
level of $^{111}$In-WBC and persistently low values for $^{99}$Tc-m.-
WBC ($P < 0.05$).

The biodistribution data (see Table 1) confirmed the
scintigraphic data obtained at 48 h ($^{111}$In-labelled pre­
parations) and 20 h ($^{99}$Tc-m.-labelled preparations) post­
injection. Abscess uptake and abscess-to-muscle ratios
were high for both $^{111}$In-WBC and $^{111}$In-liposomes.
Abscess uptake of $^{99}$Tc-m.-liposomes was higher than that of
$^{99}$Tc-m.-WBC (0.11 ± 0.01 vs 0.03 ± 0.003 %ID g$^{-1}$; $P < 0.01$), as were the abscess-to-muscle ($P < 0.05$) and
abscess-to-bone marrow ratios ($P < 0.05$). The low
blood levels of $^{99}$Tc-m.-WBC resulted (despite lower
abscess uptake) in relatively high abscess-to-blood ratios
compared with $^{99}$Tc-m.-liposomes ($P < 0.01$). Both the
$^{111}$In- and the $^{99}$Tc-m.-labelled liposomes showed higher
blood levels than the $^{111}$In- and $^{99}$Tc-m.-WBC ($P < 0.01$
and $P < 0.001$, respectively). $^{111}$In-WBC and $^{111}$In-lipo­
some uptake was very similar in all organs except the
spleen, where it was markedly higher for $^{111}$In-WBC
(3.25 ± 0.12 vs 0.70 ± 0.07 %ID g$^{-1}$; $P < 0.001$).
Although less striking than for the $^{111}$In-labelled prod­
ucts, splenic uptake of $^{99}$Tc-m.-WBC was higher than that
of $^{99}$Tc-m.-liposomes (0.66 ± 0.14 vs 0.35 ± 0.07 %ID g$^{-1}$;
$P < 0.05$). Lung and duodenal uptake of $^{99}$Tc-m.-lipo­
somes were higher than those of $^{99}$Tc-m.-WBC ($P < 0.01$).

Discussion

Stealth$^R$ liposomes labelled with either $^{111}$In or $^{99}$Tc-m.
depicted focal abscess as well as $^{111}$In-labelled leu­
kocytes. Abscess accumulation of $^{111}$In-WBC was initially
fast and high compared with both liposome formulations.
However, by 4 h post-injection this difference had

disappeared. The Stealth® liposomes labelled with either ⁹⁹ᵐTc or ¹¹¹In showed similar abscess uptake on scintigraphy. In previous studies using a rat model of infection, absolute abscess uptake of liposomes appeared to be higher than in the present study [9, 10]. However, the present study was not only performed in a different species, but also the inflammatory response was much lower in the rabbits employed. We were forced to use relatively low S. aureus doses (approximately 4 x 10⁸ CFU per kg body weight in rabbits vs 5 x 10⁸ CFU per kg body weight in rats), since a higher bacterial load causes sepsis and subsequent mortality. In contrast to the other three formulations, ⁹⁹ᵐTc-WBC showed relatively low abscess uptake. This could not be explained by the poor quality of the radiopharmaceutical, since (for both ¹¹¹In-WBC and ⁹⁹ᵐTc-WBC) the leukocytes were morphologically intact and the two in vivo quality requirements were met: fast pulmonary transit and low liver uptake [18].

With regard to the kinetics of the radiopharmaceuticals, both the label and the pharmaceutical formulation (cell or liposome) played an important role. Whole-body retention was mainly determined by the radiolabel and the labelling method. In contrast to the ¹¹¹In formulations, which were totally retained in the body, the ⁹⁹ᵐTc-labelled agents showed considerable excretion. There was significantly less ⁹⁹ᵐTc excretion when labelled liposomes (10% ID over 20 h) were used compared with ⁹⁹ᵐTc-WBC (30% ID over 20 h). This could be explained by the purification procedure of the ⁹⁹ᵐTc-liposomes, which removes the majority of unbound ⁹⁹ᵐTc-HMPAO (resulting in more than 95% radiochemical purity of the ⁹⁹ᵐTc-liposomes). ⁹⁹ᵐTc-WBC can only be purified by repeated washing of the cell suspension with 5% glucose solution, while gel filtration is impossible. In contrast to whole-body retention, blood clearance of the radiopharmaceuticals was determined by the pharmaceutical formulation: both leukocyte preparations cleared significantly faster than the labelled liposomes, resulting in relatively lower background activity of the labelled leukocytes, especially at the earlier time points.

The most striking difference in biodistribution between leukocytes and liposomes was the relatively low splenic uptake of the latter. In humans, this would not only improve image quality in the upper abdomen, but would also reduce the radiation burden to the spleen and long-living T-lymphocytes, especially when using ¹¹¹In [19]. In liver, kidney and bone marrow, uptake of the labelled WBC and liposomes was similar. For the ⁹⁹ᵐTc preparations, lung uptake of liposomes was higher than that of leukocytes. This was most probably related to the higher blood level of ⁹⁹ᵐTc-liposomes. This may also have been the case for duodenal wall activity, especially since the ⁹⁹ᵐTc-liposome images revealed a much clearer picture of the abdomen than the ⁹⁹ᵐTc-WBC images. Similar to the lower renal excretion rate of ⁹⁹ᵐTc-liposomes compared with ⁹⁹ᵐTc-WBC, the lower intestinal activity could again be explained by the extra purification required to remove non-liposomal ⁹⁹ᵐTc-HMPAO.

When comparing the labelled Stealth® liposomes with non-PEGylated liposomes, liver and splenic uptake was much lower than that of non-PEGylated larger liposomes [20, 21]. Also, bone marrow uptake is lower for Stealth® liposomes. Blood clearance and uptake of Stealth® and non-PEGylated ⁹⁹ᵐTc-labelled liposomes in
radioactivity is also similar for both formulations. Overall, targeting of the infectious focus with \(^{99}\text{Tc}^m\)-Stealth\(^R\) liposomes is at least as good as, or even better than, that of \(^{99}\text{Tc}^m\)-non-PEGylated liposomes [10, 20].

Given the similar in vivo characteristics of labelled liposomes and labelled leukocytes, the advantage of the liposome formulation would be the continuous availability of a high-quality, \(^{99}\text{Tc}^m\)-labelled radiopharmaceutical that can be prepared easily from a lyophilized kit without the need to handle blood. In patient care, \(^{99}\text{Tc}^m\)-labelled liposomes would provide an attractive alternative to the laborious method of labelled leukocytes, especially in acute infectious disease.
