Recent studies have suggested the use of lipoproteins as an adjuvant treatment of lethal gram-negative infections. However, other important microorganisms for the etiology of sepsis, such as Candida species, grow better in lipid-rich environments. We investigated the effect of hyperlipoproteinemia on systemic candidiasis in low-density-lipoprotein-receptor-deficient (LDLR-/-) mice, in which the plasma LDL concentration is increased seven to nine times (12), were significantly protected not only against lethal endotoxemia but also against lethal Klebsiella pneumoniae infection (21). In addition, an infusion of lipoproteins in rats protected the animals against mortality due to gram-negative bacterial sepsis in a model of cecal ligation and puncture (24). Taken together, these experiments demonstrate the capacity of lipoproteins to neutralize LPS and support their potential use as adjuvants in the therapy of sepsis.

On the other hand, earlier in vitro studies of lipid-containing parenteral solutions introduced for clinical use suggested that certain microorganisms, such as C. albicans and Staphylococcus aureus, grew better in a lipid-rich environment (5, 9, 16). Therefore, it is important to know the effect of hyperlipoproteinemia on the outcome of a systemic infection with these organisms before suggesting the application of infusion with lipoproteins as an adjuvant therapy in sepsis. In the present study, we assessed the influence of hyperlipoproteinemia on experimental systemic candidiasis in LDLR-/- mice.

MATERIALS AND METHODS

Animals. Homozygous C57BL/6 LDLR-/- mice and wild-type littermates were obtained from Jackson Laboratory (Bar Harbor, Maine) as mating pairs and bred in our local facility. For experiments, 6- to 8-week-old mice, weighing 20 to 25 g, were used. The animals were fed standard laboratory chow (Hope Farms, Woerden, The Netherlands) and housed under specific-pathogen-free conditions. The experiments were approved by the ethical committee for animal experiments at the Catholic University Nijmegen.

C. albicans infection. C. albicans (strain UC820), maintained on agar slants at 4°C, was inoculated into 100 ml of Sabouraud broth and cultured for 24 h at 37°C. After three washes with pyrogen-free saline by centrifugation at 1,500 x g, the suspension was diluted to the appropriate concentration with pyrogen-free saline. The viability of yeast cells was at least 99%, as confirmed by plating serial dilutions on Sabouraud dextrose agar plates. Mice were injected intravenously (i.v.) in the retro-orbital plexus with 107 CFU of C. albicans. Survival was assessed daily for 14 days in groups of at least 15 animals. In separate groups, after 4 h and 1 and 3 days, subgroups of five mice were killed by cervical dislocation and blood samples were collected for the measurement of plasma cytokine concentrations.
The outgrowth of microorganisms from the livers, spleens, and kidneys of animals was quantified on days 3 and 12 after *C. albicans* infection. For this purpose, the organs were removed aseptically, weighed, and homogenized in sterile saline in a tissue grinder. The number of viable *C. albicans* cells in tissue samples was determined by plating serial dilutions on Sabouraud dextrose agar plates as described previously (15), and CFU were counted after overnight incubation at 37°C. The results were expressed as the log CFU per gram of tissue.

### C. albicans binding studies

*In vitro.* Resident peritoneal macrophages were harvested by rinsing the peritoneal cavity aseptically with cold phosphate-buffered saline containing 0.3% (wt/vol) sodium citrate. After centrifugation, cells were resuspended in RPMI 1640 medium (Dutch modification: Flow Laboratories, Irvine, United Kingdom) containing 1 mM pyruvate, 2 mM L-glutamine, and 100 µg of gentamicin per ml and incubated for 4 h at 37°C (106/well) in 96-well microtiter plates (Costar Corporation, Cambridge, Mass.). Nonadherent cells were discarded, and the remaining cell population consisted of more than 90% macrophages, as assessed by light microscopy. Heat-killed (30 min, 100°C) *C. albicans* cells were radioiodinated by the iodogen method (13, 14). Two hundred microliters of suspensions containing 106 microorganisms in RPMI 1640 medium (Costar) infected with 106 CFU/ml. Two hundred microliters of suspensions containing 102 microorganisms in RPMI 1640 were added to peritoneal macrophages and incubated at 37°C. After 24 h, supernatants were collected and stored at −70°C until assayed. To the remaining macrophages, 200 µl of RPMI 1640 was added, and cells were disrupted by three freeze-thaw cycles to determine the cell-associated cytokine contents. The samples were stored at −70°C until assayed.

#### Cytokine measurements

*TNF-α, IL-1α, and IL-1β concentrations were determined by specific radioimmunoassays developed in our laboratory, as previously described (21).*

#### Results

**C. albicans infection.** Plasma cholesterol concentrations decreased significantly during *C. albicans* infection in both mouse strains (*P < 0.05*) but remained three to four times higher in LDLR−/− mice than in control mice (*P < 0.01*) (Table 1). The initial plasma triglyceride levels in LDLR−/− mice were twice higher than those of controls (*P < 0.01*). Four hours after infection, triglyceride levels decreased significantly in LDLR−/− mice (*P < 0.05*) and only marginally in control animals (*P > 0.05*) (Table 1). The triglyceride levels 4 h after *C. albicans* infection did not differ significantly between the two mouse strains (*P > 0.05*) (Table 1). After i.v. injection of either 105 or 107 CFU of *C. albicans*, LDLR−/− mice died significantly earlier than did control animals (*P < 0.05*) (Fig. 1).

One day after infection with 107 CFU of *C. albicans*, yeast outgrowth in the kidneys of LDLR−/− mice was significantly higher compared with that of controls; 3 days after infection, outgrowth of *C. albicans* was increased in both the kidneys and livers of LDLR−/− mice (Table 2). No difference in the outgrowth of *C. albicans* in the spleen was detected between the two mouse strains (Table 2).

#### Statistical analysis

The survival curves for control and LDLR−/− mice were below the detection limit and IL-1α concentrations were higher in LDLR mice than in controls (140 ± 22 versus 78 ± 48 µg/ml, respectively; *P < 0.05*). Circulating IL-1β concentrations were similar in both strains (56 ± 29 versus 37 ± 28 µg/ml, respectively; *P > 0.05*). Plasma TNF-α concentrations were significantly higher in LDLR−/− mice compared with those of control animals at both 24 (42 ± 5 versus 18 ± 4 µg/ml, respectively; *P < 0.01*) and 72 (302 ± 237 versus 98 ± 88 µg/ml, respectively; *P < 0.02*) h after infection (Fig. 2). No differences in plasma IL-1α and IL-1β concentrations were observed at these time points (Fig. 2).

#### In vitro cytokine production

We investigated the capacity of peritoneal macrophages of both mouse strains to produce cytokines when stimulated in vitro with heat-killed *C. albicans*. Compared with those of controls, the TNF-α concentrations in supernatants from macrophages of LDLR−/− mice were significantly higher (Fig. 3a). The IL-1α and IL-1β concentrations were only marginally increased (Fig. 3a). The cell-associated IL-1α concentration was significantly increased in macrophages of LDLR−/− mice, but the cell-associated TNF-α and Table 1. Plasma cholesterol and triglyceride concentrations before and 4 h after *C. albicans* infection in LDLR−/− and C57BL/6J mice.

<sup>a</sup>Data are means ± standard deviations of pooled data from two experiments with 10 animals per group. *, P < 0.01; **, P < 0.05.

IL-1β concentrations did not differ between the two mouse strains (Fig. 3b).

**C. albicans binding.** To investigate the total binding of C. albicans to macrophages from the two mouse strains, we incubated radioiodinated C. albicans cells with macrophages (5:1 ratio) and determined the amounts bound to macrophages after 5, 10, and 30 min of incubation. The binding of yeast cells to macrophages of LDLR<sup>−/−</sup> mice was increased and more rapid compared to that of control macrophages (Fig. 4).

**Growth of C. albicans in vitro.** To investigate whether the outgrowth of C. albicans in the organs of LDLR<sup>−/−</sup> mice is due to enhanced growth of yeast cells in a lipoprotein-rich environment, we compared the in vitro growth of 10<sup>6</sup> CFU of C. albicans in plasma samples (diluted 1:1 with Sabouraud medium) of LDLR<sup>−/−</sup> mice and controls. The capacity of LDLR<sup>−/−</sup> plasma to inhibit the outgrowth of C. albicans was decreased compared with that of control plasma, as shown by the growth of C. albicans in the two types of plasma samples after 12 [7.2 ± 2.4] × 10<sup>3</sup> versus [2.4 ± 1.5] × 10<sup>3</sup> CFU/ml, respectively; P < 0.05] and 24 [(4.2 ± 1.6] × 10<sup>3</sup> versus [1.5 ± 1.0] × 10<sup>3</sup> CFU/ml, respectively; P < 0.05] h of incubation.

**DISCUSSION**

The main conclusion from the present study is that hyperlipoproteinemia has deleterious effects on the outcome of severe C. albicans infection, in contrast to gram-negative bacterial infections. We have shown that LDLR<sup>−/−</sup> mice, with seven- to nine-times-higher LDL levels, are more susceptible to C. albicans infection than are their wild-type littermates. The earlier mortality of LDLR<sup>−/−</sup> mice was associated with increased outgrowth of C. albicans in their organs, and these mice produced significantly more proinflammatory cytokines than did control mice.

In general, mortality after infection may be due to lethal cytokinemia or to functional impairment by the growth of microorganisms in the organs of an animal. The increased susceptibility of LDLR<sup>−/−</sup> mice to C. albicans is likely to be due to the latter mechanism, because C. albicans did not induce an impressive cytokinemia. The hypothesis that cytokines are not responsible for the deaths of animals during C. albicans infection is in agreement with studies showing that the stimulation of neutrophils and macrophages by TNF and IL-1 enhanced their capability to kill C. albicans cells (6, 29), whereas anti-TNF antibodies (26) or pharmacologic inhibition of proinflammatory cytokines proved to be deleterious during severe C. albicans infection (20). Thus, proinflammatory cytokines seem to play a beneficial rather than a deleterious role in the defense against C. albicans. It should be noted that despite the greater cytokine response, LDLR<sup>−/−</sup> mice were not protected against C. albicans infection, probably due to the overwhelming outgrowth of yeast cells in their organs.

It may be hypothesized that the enhanced outgrowth of C. albicans in the organs of LDLR<sup>−/−</sup> mice is due to elevated lipoprotein concentrations. Normal serum has a candidicidal effect (22), and as shown by in vitro growth experiments, this property was significantly decreased in plasma samples from LDLR<sup>−/−</sup> mice. This effect may be due to the use of lipoproteins as a nutrition factor by C. albicans, as has been suggested by earlier studies showing increased growth of C. albicans in lipid-containing parenteral solutions compared with that in formulations without lipid contents (5, 9, 16). Another possible mechanism by which lipoproteins could influence C. albicans growth is interaction with other plasma factors. We cannot
exclude the possibility that plasma candidicidal factors, such as platelet microbicidal protein (32) and the calprotectin complex (19), are bound and inactivated by lipoproteins.

The higher cytokine concentrations during infection in LDLR−/− mice, compared with those of controls, were probably at least in part a response of the host against enhanced C. albicans outgrowth in the organs of LDLR−/− mice. However, surprisingly, stimulated in vitro with heat-killed C. albicans, macrophages of LDLR−/− mice produced significantly more TNF-α and IL-1α than macrophages of control mice did. Most likely, this was due to the observed increased binding of C. albicans to macrophages of LDLR−/− mice compared with that of control macrophages. This phenomenon may be explained by the influence of constitutively increased lipoprotein concentrations in LDLR−/− mice on the Candida-binding proteins on macrophage. It has been shown previously that hypercholesterolemia is able to modify the number and clustering of other receptors, such as the LPS receptor CD14 (7, 25). Earlier, we observed similar higher binding of radiolabelled LPS to macrophages of LDLR−/− mice, followed by higher cytokine production (21). Thus, similar changes in the number and/or clustering of Candida-binding proteins may facilitate the binding of C. albicans to macrophages of LDLR−/− mice, with a subsequent increase in cytokine production. Hyperlipoproteinemia could also modify the hydrophobicity of cells, which may also influence the adherence of C. albicans to macrophages, as has been shown for endothelial cells (10). Which of these mechanisms is responsible for the observed increase in cytokine production by macrophages of LDLR−/− mice is under study.

An alternative desirable experiment to our model in order to investigate the influence of hyperlipoproteinemia in C. albicans infection would have been to infuse lipoproteins into animals before and during infection. However, an infusion of lipoproteins into mice is not possible and other models of lipoprotein infusion in rabbits (11) and rats (24) are short-term models that are not suitable for sustained lipid infusion during systemic candidiasis. Therefore, the genetically modified mouse model is a good alternative for studying the in vivo effects of hyperlipoproteinemia in models of sustained infection.

In conclusion, hyperlipoproteinemia has deleterious effects on the course of acute disseminated C. albicans infection, in contrast to its beneficial effect in gram-negative infection. Although no epidemiological studies have been done to show a relationship between hyperlipoproteinemia and increased susceptibility to C. albicans, an infusion of lipoproteins into a patient with disseminated candidiasis under the presumptive diagnosis of gram-negative sepsis may prove deleterious. These divergent effects of hyperlipoproteinemia should be taken into account when the use of lipoproteins as an adjuvant treatment of sepsis is considered.
