Abstract

Introduction: We present a case of facioscapulohumeral muscular dystrophy (FSHD) with a diaphragm paralysis as the primary cause of ventilatory failure. FSHD is an autosomal dominant inherited disorder with a restricted pattern of weakness. Although respiratory weakness is a relatively unknown feature in FSHD, it is not uncommon.

Methods: We report on the clinical findings of a 68-year-old male who presented with severe dyspnea while supine.

Results: Supplementing our clinical findings with laboratory, electrophysiological and radiological performances led to the diagnosis of diaphragm paralysis. Arterial blood gas in sitting position without supplemental oxygen showed a mild hypercapnia. His sleep improved after starting non-invasive ventilation and his daytime sleepiness disappeared.

Discussion: We conclude that in patients with FSHD who have symptoms of nocturnal hypoventilation, an adequate assessment of the diaphragm is recommended. This is of great importance as we know that nocturnal hypoventilation can be treated effectively by non-invasive ventilation.

Introduction

Facioscapulohumeral muscular dystrophy (FSHD) is an autosomal dominant inherited disorder with a restricted pattern of weakness and is the third most common form of dystrophy [1]. In over 95% of the patients a deletion of a 3.3 kb tandem repeat, D4Z4, on chromosome 4q35 is present (FSHD type 1). In some cases (FSHD type 2), D4Z4 chromatin relaxation and stable double homeobox (DUX4) expression occur in the absence of D4Z4 array contraction [2]. FSHD type 1 and 2 are clinically characterized by asymmetric involvement of muscles in the facial, upper extremity, trunk and lower extremity region with variable severity (Table 1).

Although respiratory weakness is a relatively unknown feature of FSHD, it is not uncommon; one study reported that almost all of the patients will develop restrictive lung disease and 10–20% will suffer from pulmonary complications (Table 2).

Patients with FSHD may become respiratory insufficient if they have progressive weakness of respiratory muscles and/or a scoliosis, most likely when there are other signs of functionally severe impairment such as the need to use a wheelchair [4]. In this case report we present a patient with FSHD who had a diaphragm paralysis as the primary cause of ventilatory failure.

He was treated successfully with non-invasive positive pressure ventilation.

Case report

In 2008, at the age of 68, this man was diagnosed with Facioscapulohumeral muscular dystrophy (FSHD) type 1 (5 units 4A161).

Abbreviations: FSHD, facioscapulohumeral muscular dystrophy; DUX4, double homeobox; PSG, polysomnography; FVC, forced vital capacity; kPa, kilopascal; pH, acidity level; paCO2, partial pressure of arterial carbon dioxide; paO2, partial pressure of arterial oxygen; HCO3, bicarbonate; tcpCO2, transcutaneous carbon dioxide; SpO2, oxygen saturation; NIPPV, non-invasive positive pressure ventilation.

His medical history mentioned also psoriasis, high blood pressure for which he used bisoprolol, irbesartan, methotrexate and folate. He had also undergone surgery for penis carcinoma. His first complaints of muscle weakness were noticed at the age of 20 during a physical exam test. Exercise tolerance had been decreasing over the last 3–5 years. The last year he experienced severe dyspnea when lying in supine position. He was referred to our hospital to evaluate his respiratory impairment. Normally he slept from 11 PM till 7 AM, did not snore and because of breathlessness in supine position he preferred to sleep on his side with the top of the bed in uplift position. In the morning he woke up reasonably fit without a headache. During daytime he experienced fatigue and sleepiness, as do many FSHD patients [5,6], and he had to take a nap every afternoon.

The patient could still walk a short distance and up a flight of stairs, but this caused shortness of breath, and a mild tachypnea.

On physical examination, his weight was 97 kg, length 1.79 m, Body Mass index 29.7 kg/m². He could not lift his arms above shoulder height. There was atrophy and muscle weakness of proximal as well as distal upper and lower extremities, back and abdominal muscles, but no signs of scoliosis. The Ricci score for clinical severity of FSHD was 3 [3]. Resting heart rate: 70 beats/minute and resting respiratory rate 18 breaths/minute. In supine position there was paradoxical abdominal breathing and his respiratory rate increased. Arterial blood gas in sitting position without supplemental oxygen: acidity level (pH) 7.41, partial pressure of arterial carbon dioxide (paCO₂) 6.1 kilopascal (kPa), partial pressure of oxygen (paO₂) 9.7 kPa, bicarbonate (HCO₃⁻) 28.6 mmol/l, oxygen-saturation 95%. Nocturnal registration with the Tosca® transcutaneous monitor, before starting the chronic ventilatory support, showed a mean transcutaneous carbon dioxide (tcpCO₂) of 7.8 kPa (4–6 kPa is normal) and a mean oxygen saturation (SpO₂) of 91% (>92% is normal) [7]. The lowest saturation was 65% (Fig. 1).

To exclude that the patient had an obstructive sleep apnea syndrome a polysomnography (PSG) was performed [5,8,9]. The PSG showed a disturbed sleep with short awakenings and an apnea/hypopnea index of 2/hour (<5 is normal). Pulmonary function tests showed a decline in forced vital capacity (FVC) of 1.5 L when moving from sitting to supine position: FVC sitting 2.60 L (59% predicted), in supine position 1.10 L (25% predicted). Fluoroscopy of the diaphragm in supine position during a sniff maneuver revealed paradoxical diaphragm movement on both sides.

Results

To relieve his physical complaints and improve his alveolar hypoventilation he started non-invasive positive pressure ventilation.

![Fig. 1. Nocturnal transcutaneous registration of carbon dioxide (mean 7.8 kPa) and oxygen saturation (mean 91%) before starting ventilation.](image-url)
ventilation (NIPPV) during the night. The ventilator was set in the
pressure assisted controlled mode with an inspiratory pressure of
24 cm H2O, a positive end expiratory pressure of 8 cm H2O and a
frequency of 15 per minute. The patient used the ventilator every
night with a mean usage of 7 h per night. His relationship with the
ventilator was dual; he thought of it as an enemy because he had
problems accepting the necessity to be ventilated, but also as a
friend because it provided him better sleep and more energy during
the day. While the vital capacity did not change after starting
NIPPV, the arterial blood gas during the day at rest without venti-
lation did improve: pH 7.41, pCO2 5.9 kPa, pO2 11 kPa, HCO3
28 mmol/l, oxygen-saturation 97%. Nocturnal registration one year
after starting the NIPPV showed a mean tcpCO2 of 6.1 kPa and a
mean SpO2 of 94% (Fig. 2).

By using NIPPV the patient could now sleep in supine position.
He slept better and he experienced more energy during daily ac-
tivities. In addition he did not fall asleep anymore during daytime
hours.

Discussion

This patient with FSHD had respiratory failure due to bilateral
diaphragm paralysis as shown by the large drop in the vital capacity
when changing from sitting to supine position in combination with
paradoxical diaphragm movement during the sniff maneuver. A recent study concluded that the diaphragm should in principle not
be paralyzed in patients with FSHD and therefore the authors did
not recommend an evaluation of the diaphragm [10]. However, in
that study patients were included who did not have symptoms of
hypoventilation like morning headache, fatigue and daytime
sleepiness, so it could be expected that the lung function was only
mildly impaired. It is known that patients with FSHD can have
complaints due to hypoventilation [4]. As an assessment of the vital
capacity in both sitting and supine position and fluoroscopy of the
diaphragm was not mentioned in that study, a paralysis of the
diaphragm could have been missed as the primary cause of hypo-
ventilation. Actual search and documentation of nocturnal hypo-
ventilation is relevant since it can be treated effectively by NIPPV.
We conclude that in patients with FSHD, who have symptoms of
nocturnal hypoventilation such as morning headache, fatigue and
daytime sleepiness, an adequate assessment of the diaphragm is
recommended.

Author contribution to the manuscript

A. Hazenberg – writing and submitting the manuscript.
Dr. N. van Allen – revision of the manuscript for important in-
tellectual content.
N.B.M. Voet – acquisition and interpretation of data.
Prof. H.A.M.Kerstjens – critical revision of the manuscript for
important intellectual content.
Dr. P.J.Wijkstra – final approval of the version to be submitted
and supervision.
