Associated Links Among Smoking, Chronic Obstructive Pulmonary Disease, and Small Cell Lung Cancer: A Pooled Analysis in the International Lung Cancer Consortium

Abstract

Background: Despite their high prevalence, the associations among smoking, chronic obstructive pulmonary disease (COPD), and small cell lung cancer (SCLC) are poorly understood.

Methods: In a pooled analysis of 66 population-based cancer registries, we assessed 173,290 incident cases of lung cancer from six continents, with a median follow-up of 4.6 years (1983–2013). We studied ever smoking before diagnosis, COPD (defined as chronic respiratory disease or chronic bronchitis and/or emphysema), and SCLC (defined as anaplastic carcinoma or oat cell carcinoma). We used multivariable Cox proportional hazards models to estimate the association between each outcome and all-cause mortality.

Results: Among all lung cancers, 30% of cases were diagnosed in smokers, 11% of cases were diagnosed in former smokers, 11% of cases were diagnosed in current smokers, and 58% of cases were diagnosed in never smokers. Of all lung cancers, 8% were diagnosed in patients with COPD. Among all lung cancers, 20% were diagnosed in patients with SCLC. The risk of lung cancer mortality was higher among former smokers than among never smokers (hazard ratio [HR] = 1.43, 95% confidence interval [CI] = 1.36–1.50). The risk of lung cancer mortality was higher among current smokers than among never smokers (HR = 1.55, 95% CI = 1.48–1.62). The risk of lung cancer mortality was higher among patients with COPD than among never smokers (HR = 1.50, 95% CI = 1.38–1.63). The risk of lung cancer mortality was higher among patients with SCLC than among never smokers (HR = 1.99, 95% CI = 1.68–2.36).

Conclusion: Smoking and COPD are important risk factors for lung cancer mortality. Preventive strategies targeting smoking and COPD may be beneficial for reducing lung cancer mortality.

Background: The high relapse and mortality rate of small-cell lung cancer (SCLC) fuels the need for epidemiologic study to aid in its prevention.

Methods: We included 24 studies from the ILCCO collaboration. Random-effects panel logistic regression and cubic spline regression were used to estimate the effects of smoking behaviors on SCLC risk and explore their non-linearity. Further, we explored whether the risk of smoking on SCLC was mediated through COPD.

Findings: Significant dose–response relationships of SCLC risk were observed for all quantitative smoking variables. Smoking pack-years were associated with a sharper increase of SCLC risk for pack-years ranged 0 to approximately 20. The former smokers with longer cessation showed a 43\% reduction in SCLC risk vs. subjects who had quit smoking <5 years. Compared with non-COPD subjects, smoking behaviors showed a significantly higher effect on SCLC risk among COPD subjects, and further, COPD patients showed a 1.86-fold higher risk of SCLC. Furthermore, smoking behaviors on SCLC risk were significantly mediated through COPD which accounted for 0.70 to 7.55\% of total effects.

Interpretation: This is the largest pooling study that provides improved understanding of smoking on SCLC, and further demonstrates a causal pathway through COPD that warrants further experimental study.

1. Introduction

Small cell lung cancer (SCLC) comprises approximately 15–18\% of all lung cancers worldwide (Fruh et al., 2013). SCLC is the most aggressive subtype of lung cancer and is characterized by rapid doubling time, high growth fraction, and early widespread metastasis (Kalemkerian et al., 2013). Despite high response rates to initial treatment, SCLC usually relapses and becomes refractory to treatment within one year. The median survival is 14–20 months for limited SCLC and 9–11 months for extensive SCLC (Kalemkerian et al., 2013). These statistics highlight the need for new tools to aid in diagnosis and prevention.

Smoking is the major risk factor for SCLC (Pesch et al., 2012; Engeland et al., 1996; Freedman et al., 2008). However, previous studies were limited in sample size and statistical power to estimate more precise effect size of smoking on SCLC risk as well as the non-linear exposure–response relationships, which have been thoroughly explored in the previous non-small cell lung cancer (NSCLC) studies (Zhai et al., 2014a, b). Furthermore, smoking is also an independent risk factor for chronic obstructive pulmonary disease (COPD), which shares similar genetic and biological characteristics to lung cancer (Houghton, 2013; Roca et al., 2012; Schwartz and Ruckdeschel, 2006; Young and Hopkins, 2011), while concomitant COPD is also an independent risk factor for chronic obstructive pulmonary disease (COPD), which shares similar genetic and biological characteristics to lung cancer (Houghton, 2013; Roca et al., 2012; Schwartz and Ruckdeschel, 2006; Young and Hopkins, 2011), while concomitant COPD and COPD, which shares similar genetic and biological characteristics to lung cancer (Houghton, 2013; Roca et al., 2012; Schwartz and Ruckdeschel, 2006; Young and Hopkins, 2011), while concomitant COPD has not been fully examined with regard to SCLC risk (Purdue et al., 2007; Fan et al., 2011). Precise understanding of the association between smoking, COPD, and SCLC using a large sample size will shed light on its pathogenesis.

To address these knowledge gaps, we conducted a pooling analysis of 24 case–control studies in the International Lung Cancer Consortium (ILCCO) that in total included 43,964 SCLC cases and 37,942 cancer-free controls. We examined: 1) exposure–response relationships between SCLC risk and cigarette smoking indicators, including cumulative smoking, age of initiation, and time since quitting smoking; 2) the association between smoking and mortality risk of COPD and SCLC risk; and 3) the interaction and mediation effects of COPD and cigarette smoking on SCLC risk.

2. Methods

2.1. Ethics

Individual studies were approved by their respective ethics committees.
2.4. Smoking and Other Factors

All studies collected information on lifetime history of cigarette smoking, including age of initiation of smoking, duration, intensity, and time since quitting for former smokers. To explore the non-linear association between smoking and SCLC, we generated common categorical variables related to smoking status (never smoker defined as no cumulative smoking, current smoker defined as cumulative smoking of any amount plus time since quitting smoking less than or equal to 1 year, and former smoker defined as smokers who had quit more than 1 year before diagnosis or interview), daily smoking intensity (1–9, 10–19, 20–29, 30–39, and 40 or more cigarettes/day), smoking duration (1–19, 20–29, 30–39, 40–49, and 50 or more years), and lifetime cumulative smoking (1–19, 20–39, 40–59, 60–79, and 80 or more pack-years; one pack-year being equivalent to 20 cigarettes/day smoked during 1 year). Former smokers were further categorized according to age of smoking initiation (less than 15 years, 15–19, 20–25, 25–30, or more than 30 years) and time since quitting (≤5, 5–9, 10–19, or 20 or more years).

Other variables included in the pooled analysis were gender, age at diagnosis or interview, geographical region (North America, Europe, and Asia and Oceania), self-reported race (Asian, Black, White, Hawaiian, Hispanic, Other), family history of lung cancer (yes, no), and education level (non, elementary, vocational, postsecondary, university).

2.5. Statistical Analysis

2.5.1. Non-linear Exposure–Response Relationships of Smoking Behaviors on SCLC

The odds ratios (ORs) of SCLC and their 95% confidence intervals (95% CIs) for daily smoking intensity, duration of smoking, lifetime cumulative smoking, age of smoking initiation, and time since quitting were estimated using random-effects panel logistic regression (Conway, 1990). This multilevel model takes account of the variation among studies (panels), and study heterogeneity, during model fitting. The ρ, ranging from 0 to 1, represents the proportion of the total variance contributed by the panel (study)-level variance component. When ρ is zero, the panel-level variance component is negligible, and the estimators from the panel logistic regression are no different from that from the traditional logistic regression. Age at diagnosis and gender were adjusted for in all the regression models. Trends of SCLC risk across smoking categories were evaluated by fitting the categorical smoking variables into an ordinal regression model (Armstrong and Sloan, 1989). To better visualize the exposure–response relationship, we plotted cumulative smoking, age of smoking initiation, and time since quitting smoking with the SCLC risks using estimates from restricted cubic spline models (Hastie and Tibshirani, 1995; Campbell, 1996). The non-linear association was explored by applying the likelihood test to compare the spline model to its nested linear model. Subgroup analyses were performed stratified by COPD status, gender, study area (Caucasian-dominated areas vs. non-Caucasian dominated areas), source of controls (hospital-based controls vs. population-based controls), and 1st degree family history of lung cancer (yes vs. no), and the difference of risk effects between subgroups was evaluated by including the interaction term of smoking and stratifying variable into the model.

2.5.2. Interaction and Mediation Analyses

The associations between cumulative smoking and SCLC risk were further tested in subgroups with and without preexisting COPD. We conducted the Wald test for effect modification from COPD by adding an interaction term. It is well-established that smoking is the risk to both COPD and SCLC, and COPD is a risk factor to SCLC. To explore whether the effect of smoking on the risk of SCLC is mediated through COPD, the VanderWeele’s mediation analysis was performed (VanderWeele and Vansteelandt, 2010). The smoking effect on SCLC was decomposed to two parts: the indirect effect which represents the effect of smoking is mediated through COPD and the direct effect which represents the effect of smoking on SCLC by pathways other than COPD. To obtain direct and indirect effects of smoking on SCLC risk, ORs for mediation analysis in the case–control setting were calculated by combining the regression of COPD and the regression of SCLC risk (VanderWeele and Vansteelandt, 2010; VanderWeele et al., 2012). The proportion mediated was obtained by OR_d × (OR_c – 1) / (OR_d × OR_c – 1), where OR_d is the direct effect odds ratio and OR_c is the indirect effect odds ratio (Campbell, 1996).

All tests were two-sided and evaluated using SAS software (version 9.4; SAS Institute, Cary, NC) or STATA statistical package (Version 14; Stata Corp. LP, College Station, TX, USA). A P-value of less than 0.05 was considered statistically significant.

3. Results

3.1. Characteristics of Study Populations

In the 24 studies with recruitment initiated since 1969, 4346 SCLC patients and 37,942 non-SCLC controls were identified (Table S1). Among ten studies with available COPD status, 1543 COPD and 14,665 non-COPD subjects were further analyzed to explore stratified and mediation effects. Demographic characteristics are summarized in Table 1. SCLC patients were significantly older, male-predominant, less educated, and more commonly had a family history of lung cancer than their respective controls (P < 0.01). For smoking behaviors, the proportions of current smokers/former smokers, the amount of lifetime cumulative smoking pack-years, smoking duration, and smoking intensity (cigarettes per day) in SCLCs or COPDs were significantly higher than in their respective controls, while the time since quitting smoking was significantly lower than that in controls (P < 0.01). The frequency of COPD diagnosis was higher among SCLC cases (20.6%) than controls (7.6%) (P < 0.001).

3.2. Association of Smoking Behaviors With SCLC Risk

Former smokers had a significantly higher risk on SCLC vs. non-smokers (OR, 6.21, 95% CI 5.21–7.41, P < 0.001) while a much higher risk existed among current smokers vs non-smokers (OR, 26.72, 95% CI 22.54–31.68, P < 0.001) (Table 2). A statistically significant dose–response for SCLC risk was observed for all quantitative smoking variables (Table 2). Cumulative smoking intensity (smoking pack-years) was associated with increased risk of SCLC vs. non-smokers in a significant dose–response manner [ORs ranged from 4.33 for those who had pack-years < 20 to 69.03 for those who had pack-years ≥ 80, P for trend (P_trend) < 0.001]. Smoking intensity had a
similar dose–response model (ORs from 4.35 to 10 cigarettes-per-day to 34.49 ≥ 40 cigarettes-per-day, $P_{\text{trend}} < 0.001$), as well as smoking duration (ORs ranged from 2.37 to 50 years to 48.80 ≥ 50 years, $P_{\text{trend}} < 0.001$), and age of initiation (ORs from 7.09 smoking_after_30 to 24.04 smoking_before_15, $P_{\text{trend}} < 0.001$). The former smokers with longer cessation showed a considerably decreased risk on SCLC risk in a dose–response trend vs. subjects who had quit smoking for less than 5 years [OR for those who had quit for 9–9 years (OR$_{9-9}$), 0.57, 95% CI 0.45–0.73; OR$_{10-19}$, 0.28, 95% CI 0.23–0.36; OR$_{≥20}$, 0.11, 95% CI 0.09–0.14, $P_{\text{trend}} < 0.001$]. The sensitivity analysis yielded similar results with further adjustment for study areas (Caucasian-dominated areas vs. non-Caucasian-dominated areas), source of controls (hospital-based vs. population-based), and family history of lung cancer (yes vs. no) (Table 2).

### 3.3. Stratified Analyses of Smoking Behaviors on SCLC Risk

Further, we performed the stratified analyses by COPD, gender, ethnicity, source of control, and 1st degree family history of lung cancer. All the smoking variables showed a higher effect on SCLC risk in COPD subgroup than those in non-COPD subjects with significance or borderline significance except for time since quitting smoking which was probably due to insufficient sample size (Table 2). Male smokers had a trend of stronger dose–response on SCLC risk than that in female but with a lack of statistical significance (Table S3). Smoking variables in Caucasian-dominated populations showed stronger effects on SCLC risk than those in non-Caucasian dominant populations (Table S4). No statistical significance was observed for time since quitting smoking probably due to insufficient sample size from non-Caucasian populations (Table S4).

Further, stratified analyses by control type showed a trend of higher effects of smoking behaviors on SCLC risk in the studies with population-based controls than those in the studies with hospital-based controls (Table S5). Furthermore, in stratified analysis by family history of lung cancer, smoking behaviors showed a trend of, but non-significant, stronger effects in subjects with family history of lung cancer than the others (Table S6).

### 3.4. Non-linear Exposure–Response Relationships

Further, non-linear exposure–response relationships of smoking pack-years and time since quitting smoking were explored using restricted cubic spline regression model (Fig. 1). The SCLC risk for cumulative smoking pack-years revealed an upward spline with a knot at approximately 50 pack-years ($P_{\text{non-linear}} < 0.001$); the slope of the first segment was larger than that of the second segment (Fig. 1a). The results were consistent in the subgroup analyses stratified by COPD status (Fig. 1b for non-COPD, 1c for COPD), by gender (1d for male, 1e for female), and study area (1f for Caucasian-dominated areas, 1g for non-Caucasian-dominated areas). In contrast, there were significantly decreasing trends between time since quitting smoking and SCLC risk among former smokers (Fig. 1h) which obtained consistent results among the subgroup analyses (Fig. 1i–m). We were not able to perform the cubic spline analysis among the former smokers in studies from non-Caucasian-dominated areas due to insufficient cases recruited.

### 3.5. Smoking Effect on SCLC Mediated Through COPD

Smoking behaviors were positively associated with COPD risk (Table S7). COPD status was independently associated with SCLC risk (OR, 1.86, 95% CI 1.61–2.16, $P < 0.001$) with adjustment for age, gender, and smoking pack-years. Furthermore, to explore whether the association between smoking and SCLC risk was mediated through COPD, we performed a series of mediation analyses (Table 3). A statistically significant indirect effect on SCLC risk mediated through COPD was observed for former smokers [OR$_{\text{direct}}$, 1.03, $P < 0.001$; proportion mediated (%M), 3.57%] or current smokers [OR$_{\text{direct}}$, 1.06, $P < 0.001$; %M, 5.86%], smoking pack-years (OR$_{\text{direct}}$ Per SD, 1.03, $P < 0.001$; %M, 4.99%), smoking intensity (OR$_{\text{direct}}$ per SD, 1.01, $P < 0.001$; %M, 2.52%), smoking duration (OR$_{\text{direct}}$ Per SD, 1.05, $P < 0.001$; %M, 7.55%), and time since quitting smoking (OR$_{\text{direct}}$ per SD, 0.98, $P = 0.005$; %M, 0.70%). Overall, less than 10% of smoking’s risk effect on SCLC risk was mediated through COPD (Fig. 2).

Values are presented as n (%) for categorical data or mean (standard deviation [SD]) for continuous variables. The categorical variables were tested by Fisher’s exact test and continuous variables were compared by Student t-test between groups/subgroups. The quantitative smoking variables were summarized among former or current smokers. SCLC: small cell lung cancer; COPD: chronic obstructive pulmonary disease.

*P*-value ≤ 0.01 of COPD vs. non-COPD among SCLC cases.

$P$-value < 0.01 of COPD vs. non-SCLC among overall samples.

$P$-value < 0.01 of COPD vs. non-COPD among non-SCLC subjects.
The studies (St Sauver et al., 2012). The pooling study also took advantage of the ethnic design makes this study generalizable to the other populations of SCLC (Pesch et al., 2012). The major strength of this study is its relationship among multiple quantitative smoking risk factors, COPD, and risk of SCLC. Smoking behaviors and the risk of SCLC.

The proportion of the total variance contributed by the panel (study)-level variance component. It is ranged from 0 to 1. The closer of the proportion to 0 represents the less heterogeneity among populations (St Sauver et al., 2012). The pooling study also took advantage of the well-planned questionnaires that collected data on detailed smoking behaviors such as cumulative smoking, age since smoking initiation, and time since quitting smoking, as well as COPD status.

Our study addressed the information gap regarding the non-linear exposure-response relationships between the cigarette smoking behaviors, COPD, and risk of SCLC. SCLC risk rises sharply with the first 50 pack-years of cumulative smoking, and increases continuously with further smoking. A similar steep slope with a subsequent leveling-off of lung cancer risk for intensity of smoking and a plateauing of the SCLC risks by duration of smoking were seen in previous studies (Pesch et al., 2012; Zhai et al., 2014a; Vineis et al., 2000). Findings of very high relative risks for SCLC in smokers are in agreement with experimental findings (Liu and Engelhardt, 2008; Liu et al., 2012; Zhai et al., 2014a; Vineis et al., 2000). Findings of very high relative risk of lung cancer for intensity of smoking and for extensive damage (Liu and Engelhardt, 2008; Liu et al., 2012; Zhai et al., 2014a; Vineis et al., 2000). Findings of very high relative risk of lung cancer for intensity of smoking and for extensive damage (Liu and Engelhardt, 2008; Liu et al., 2012; Zhai et al., 2014a; Vineis et al., 2000). Findings of very high relative risk of lung cancer for intensity of smoking and for extensive damage (Liu and Engelhardt, 2008; Liu et al., 2012; Zhai et al., 2014a; Vineis et al., 2000). Findings of very high relative risk of lung cancer for intensity of smoking and for extensive damage (Liu and Engelhardt, 2008; Liu et al., 2012; Zhai et al., 2014a; Vineis et al., 2000). Findings of very high relative risk of lung cancer for intensity of smoking and for extensive damage (Liu and Engelhardt, 2008; Liu et al., 2012; Zhai et al., 2014a; Vineis et al., 2000). Findings of very high relative risk of lung cancer for intensity of smoking and for extensive damage (Liu and Engelhardt, 2008; Liu et al., 2012; Zhai et al., 2014a; Vineis et al., 2000).
early as possible. The risk remains 3.59 fold higher (95% CI 2.71–7.46, \(P < 0.001\)) after 20 years’ cessation compared with never smokers. A possible mechanism for this long-term carcinogenic effect of smoking is that cigarette smoke can exert a wide range of irreversible changes in lung tissue that affect its function (Thorley and Tetley, 2007).

The risk of lung cancer in patients with COPD has long been established (Zhai et al., 2014a; Purdue et al., 2007; Raviv et al., 2011). However, most of the studies focused on the risk of overall lung cancer or NSCLC, while the relationship with SCLC was rarely explored or underpowered (Kato et al., 2011). Our analysis offers insights suggesting that 86% of increased risk of SCLC occurs in persons with COPD independent from smoking. Further, our study suggests that smoking has a higher damaging effect on lungs among subjects diagnosed of COPD than non-COPD subjects, which indicates a synergistic mechanism in lung cancer pathophysiology. This finding agrees with that of our previous study of non-small cell lung cancer (Zhai et al., 2014a). One biological explanation for this association between COPD and SCLC is that long-term pulmonary inflammation from COPD damages lung tissue and produces free radicals that may induce mutagenesis during tissue regeneration (Ballaz and Mulshine, 2003). Another potential mechanistic explanation is that
impaired mucociliary function in COPD patients could hamper the removal of harmful particles (Zhai et al., 2014b; Houtmeyers et al., 1999). Other mechanisms associated with the presence of COPD that might be associated with the inflammation and associated cytokines, development of lung cancer includes alterations to cell cycle regulation, shared genetic and epigenetic susceptibilities (Houghton, 2013). Furthermore, no study has previously investigated the role of COPD as a causative mediator between smoking and SCLC. Our study demonstrates that less than 10% of the smoking risk effect on SCLC is mediated through COPD. Wang et al. reported one-third of the effect of smoking behavior on lung cancer mediated through COPD. The findings indicate a histologically-different causal role of COPD among smoking and lung cancer, which warrants further validation and experimental study (Wang et al., 2010).

We acknowledge some limitations in our study. First, misclassification of SCLC or COPD has to be considered since our study included diverse countries in which different diagnostic criteria may apply. A pathology comparability analysis was performed by Stang et al. in a German case series; the agreement between pathologists was 94% for SCLC, and lower in never smokers (Stang et al., 2006). Second, studies included were lacking information on spirometry, and underdiagnostics of COPD was thus significant among non-COPD subjects, which is about 70% of the total population (Mannino et al., 2000; Lamprecht et al., 2015; Bednarek et al., 2008). Due to underdiagnosed COPD patients, risks of smoking behaviors among non-COPD subgroups were, to some extent, overestimated. However, physician-diagnosed COPD is compatible with spirometry-based COPD for epidemiological studies (Straus et al., 2002; Eiser et al., 2005; Murgia et al., 2014). A validation assessment also confirmed that self-reported physician–diagnosed COPD correlates with high rates of true COPD in medical records (Barr et al., 2002). Therefore, such underdiagnosis of COPD contributes to the more conservative results for the evaluation of the risk difference between COPD and non-COPD. On the other hand, a more accurate COPD diagnostic method will result in a higher stratified effect as well as stronger statistical power. Third, mediation information of COPD patients was also important to this association study. Inhaled corticosteroids (ICS) are anti-inflammatory drugs that have proven benefits for worsening COPD patients (Kew and Seniukovich, 2014), as well as a decreased risk of lung cancer in a dose–response manner (Parimon et al., 2007; Lee et al., 2013). Statins are also recognized as powerful anti-inflammatory agents beyond low-density lipoprotein cholesterol reduction (Pruefer et al., 2002), which have a beneficial role in COPD treatment including reduced risk of lung cancer (Janda et al., 2009; van Gestel et al., 2009). Inclusion of the medication information in future study increases both statistical power and clinical interpretation. Besides, the source of controls, SCLC case ascertainment, COPD verification, geographical area, and recruitment period could explain partial heterogeneity. Though we detected a significant indirect effect of smoking on SCLC risk mediated by COPD, we were not able to determine the temporal relationship between COPD and SCLC in this study, and reverse causality of the pre-diagnosed stage of SCLC could thus possibly affect COPD development as well.

5. Conclusion

This study emphasizes the non-linear association of smoking with the relative risk of SCLC. The pattern is partially supported by prior SCLC studies (Pesch et al., 2012; Vinea et al., 2000) and hypothesis-generating experiments. Smoking also has a strong effect on COPD, and COPD is an independent risk factor on SCLC, and further, a part of smoking risk effect on SCLC is mediated through COPD. The mutually shared genetic predisposition or common mechanistic pathway among smoking behaviors, COPD and SCLC warrants investigation to facilitate early detection of SCLC.

Odds ratios (OR) were in per standard deviation (SD, among all samples) increment. The SDs of smoking pack years, smoking intensity, smoking duration, age of initiation, time since quitting smoking among former smokers were 25.9 pack-years, 13.2 cigarettes per day, 17.9 years, 5.6 years, and 13.0 years, respectively.
Role of Sponsors

The sponsors of all the funding bodies had no role in the design of the study, the collection and analysis of the data, or the preparation of the manuscript.

Author Contributions

Dr. Ru-Yi Huang generated the conception, done the data analysis, interpreted the data, and wrote the manuscript. Dr. Yongyue Wei generated the conception together with analyzing the data in depth and revising the manuscript. Dr. Rayjean Hung was in charge of the data harmonization, monitor of the consortium work and offered statistical assistance for the manuscript. All authors from the ILCCO group contributed to the design and execution of the work and to the preparation and drafting critically of this report. Additionally, all had the opportunity to contribute to the interpretation of the results and to the redrafting of the report. Approval of the final report was obtained from all authors. Dr. David Christiani wrote and supervised the project concept and was responsible for the final report.

Conflicts of Interest

We declare that we have no conflicts of interest.

Acknowledgments

We thank Dr. June Carroll and the Mount Sinai Hospital Granovsky Gluskin Family Medicine Centre for helping with the recruitment of the MSH-PMH study. We thank the study participants and the Lung Cancer Study Team of the MGH Thoracic Oncology Center.

Appendix A Supplementary Data

Supplementary data to this article can be found online at http://dx.doi.org/10.1016/j.ebiom.2015.09.031.
