Measurement of spin correlation between top and antitop quarks produced in $p\bar{p}$ collisions at $\sqrt{s} = 1.96$ TeV

We present a measurement of the correlation between the spins of $t$ and $\bar{t}$ quarks produced in proton-antiproton collisions at the Tevatron Collider at a center-of-mass energy of 1.96 TeV. We apply a matrix element technique to dilepton and single-lepton+jets final states in data accumulated with the D0 detector that correspond to an integrated luminosity of 9.7 fb$^{-1}$. The measured value of the correlation coefficient in the off-diagonal basis, $O_{\text{off}} = 0.89 \pm 0.22$ (stat + syst), is in agreement with the standard model prediction, and represents evidence for a top-antitop quark spin correlation difference from zero at a level of 4.2 standard deviations.

I. INTRODUCTION

The top quark is the heaviest elementary particle in the standard model (SM) $\uparrow\downarrow$. Despite the fact that the top quark decays weakly, its large mass leads to a very short lifetime of $\approx 5 \cdot 10^{-25}$ s $\uparrow\downarrow$. It decays to a $W$ boson and a $b$ quark before hadronizing, a process that has a characteristic time of $1/\Lambda_{\text{QCD}} \approx (200 \text{ MeV})^{-1}$ equivalent to $\tau_{\text{had}} \approx 3.3 \cdot 10^{-24}$ s, where $\Lambda_{\text{QCD}}$ is the fundamental scale of quantum chromodynamics (QCD). The top quark lifetime is also smaller than the spin-decorrelation time from spin-spin interactions with the light quarks generated in the fragmentation process $\uparrow\downarrow$, $\tau_{\text{spin}} \approx m_t/\Lambda_{\text{QCD}} \approx (0.2 \text{ MeV})^{-1} \approx 3 \cdot 10^{-21}$ s $\uparrow\downarrow$. The top quark thus provides a unique opportunity to measure spin-related phenomena in the quark sector by exploiting kinematic properties of its decay products.

In proton-antiproton ($p\bar{p}$) collisions, the dominant process for producing top quarks is through top-antitop ($t\bar{t}$) quark pairs. This QCD process yields unpolarized $t$ and $\bar{t}$ quarks, but leaves the spins of $t$ and $\bar{t}$ correlated. A spin correlation observable can be defined as

$$O_{ab} = \langle (4S_t \cdot \hat{a})(S_{\bar{t}} \cdot \hat{b}) \rangle = \frac{\sigma(\uparrow\downarrow) + \sigma(\downarrow\uparrow) - \sigma(\uparrow\uparrow) - \sigma(\downarrow\downarrow)}{\sigma(\uparrow\downarrow) + \sigma(\downarrow\uparrow) + \sigma(\uparrow\uparrow) + \sigma(\downarrow\downarrow)},$$

where $S$ is a spin operator, $\hat{a}, \hat{b}$ are the spin quantization axes for the top quark ($\hat{a}$) and the antitop quark ($\hat{b}$), $\langle \rangle$ refers to an expectation value, $\sigma$ is the $t\bar{t}$ production cross section, and the arrows refer to the spin states of the $t$ and $\bar{t}$ quarks relative to the $\hat{a}$ and $\hat{b}$ axes. The strength of the correlation depends on the $\hat{t}\hat{\bar{t}}$ production mechanism $\uparrow\downarrow$. In $p\bar{p}$ collisions at a center-of-mass energy of 1.96 TeV, the correlation of spins is predicted to be $O_{\text{off}} = 0.80_{-0.02}^{+0.01}$ $\uparrow\downarrow$ in the off-diagonal spin basis, the basis in which the strength of the spin correlation is maximal at the Tevatron $\uparrow\downarrow$. The most significant contribution is from the quark-antiquark annihilation process ($q\bar{q} \rightarrow t\bar{t}$) with a spin correlation strength of $\approx 0.99$, while the gluon-gluon ($gg$) fusion process ($gg \rightarrow t\bar{t}$) has anticorrelated spins with a typical strength of $\approx -0.36$ at next-to-leading order (NLO) in QCD $\uparrow\downarrow$. Contributions to $t\bar{t}$ production from beyond the SM can have different dynamics that affect the strength of the $t\bar{t}$ spin correlation.

Evidence for $t\bar{t}$ spin correlations based on a matrix element technique $\uparrow\downarrow$ was presented by the D0 collaboration. Earlier lower precision measurements used a tem-
plate method [17, 18]. Spin correlation effects have also been measured in proton-proton (pp) collisions by two LHC collaborations, ATLAS and CMS, at a center-of-mass energy of 7 TeV [19, 22] and at 8 TeV [23, 24]. The main mechanism for $t\bar{t}$ production at the LHC is the $gg$ fusion process. The spin correlation at the LHC arises mainly from the fusion of like-helicity gluons [25].

The differences between $pp$ and $p\bar{p}$ incident channels, the different sources of spin correlation (quark-antiquark annihilation versus like-helicity $gg$ fusion), and their different collision energies, make the measurements of the strength of the spin correlation at both the Tevatron and LHC interesting and complementary.

In this letter, we present an updated measurement of the $t\bar{t}$ spin correlation strength in $p\bar{p}$ collisions at $\sqrt{s} = 1.96$ TeV. The measurement uses the statistics accumulated during 2001–2011 data taking period of the Fermilab Tevatron Collider, which corresponds to an integrated luminosity of 9.7 fb$^{-1}$, which is almost two times more than in our previous publication [16].

II. DETECTOR, EVENT SELECTION AND SIMULATION, BACKGROUND

The D0 detector is described in Refs. [26, 32]. It has a central tracking system consisting of a silicon microstrip tracker and a central fiber tracker, both located within an $\sim 2$ T superconducting solenoidal magnet. The central tracking system is designed to optimize tracking and vertexing at detector pseudorapidities of $|\eta_{\text{det}}| < 2.5$.

The liquid-argon sampling calorimeter has a central section covering pseudorapidities $|\eta_{\text{det}}| < 2.5$. There is a central section covering pseudorapidities $|\eta_{\text{det}}| > 2.5$, and two end calorimeters that extend coverage to $|\eta_{\text{det}}| \approx 4.2$, with all three housed in separate cryostats. A outer muon system, with pseudorapidity coverage of $|\eta_{\text{det}}| < 2$, consists of a layer of tracking detectors and scintillation trigger counters in front of 1.8 T iron toroids, followed by two similar layers after the toroids.

Within the SM, the top quark decays with almost 100% probability into a $W$ boson and a $b$ quark. We also include two final states: the dilepton final state ($\ell\ell$, where both $W$ bosons decay to leptons, and the lepton+jets final state ($\ell+$jets), where one of the $W$ bosons decays into a pair of quarks and one decays to a lepton and a neutrino. The $\ell+$jets and $\ell\ell$ final states contain, respectively, one or two isolated charged leptons. In both final states we consider only electrons and muons, including those from $\tau$-lepton decay, $W \rightarrow \tau\nu_\tau \rightarrow \ell\nu_\ell\nu_\tau$. We also require the presence of two $b$ quark jets, two light-quark jets from $W$ decay (in $\ell+$jets), and a significant missing transverse momentum ($p_T$) due to the escaping neutrinos.

We use the following selection criteria. In the $\ell\ell$ channels, we require two isolated leptons with $p_T > 15$ GeV, both originating from the same $p\bar{p}$ interaction vertex. The $\ell+$jets channels require one isolated lepton with $p_T > 20$ GeV. We consider electrons and muons identified using the standard D0 criteria [33, 34]. In the pseudorapidity range of $|\eta_{\text{det}}| < 2.0$ for muons, and $|\eta_{\text{det}}| < 1.1$ for electrons. In the $\ell\ell$ channels, we consider in addition forward electrons in the range of $1.5 < |\eta_{\text{det}}| < 2.5$. Jets are reconstructed and identified from energy deposition in the calorimeter using an iterative midpoint cone algorithm [35] of radius $\sqrt{(\Delta \phi)^2 + (\Delta \eta)^2} = 0.5$. Their energies are corrected using the jet energy scale (JES) algorithm [36]. All $\ell\ell$ channels also require the presence of at least two jets with $p_T > 20$ GeV and $|\eta_{\text{det}}| < 2.5$. For the $\ell+$jets final state, at least four jets must be identified with the same $p_T$ and $\eta_{\text{det}}$ cutoffs, but with the leading jet required to have $p_T > 40$ GeV. When a muon track is found within a jet cone, the JES calculation takes that muon momentum into account, assuming that the muon originates from the semileptonic decay of a heavy-flavor hadron belonging to the jet. To identify $b$ quark jets, we use a multivariate b quark jet identification discriminant that combines information from the impact parameters of the tracks and variables that characterize the presence and properties of secondary vertices within the jet [37]. We require that at least one jet is identified as a $b$ quark jet in the $\ell\ell$ channels, and at least two such jets in the $\ell+$jets channels. To improve signal purity, additional selections based on the global event topology are applied [38, 39] in each final state. A detailed description of event selection can be found in Ref. [38] for the $\ell\ell$ and in Ref. [39] for the $\ell+$jets final states.

To simulate $t\bar{t}$ events we use the next-to-leading (NLO) order Monte Carlo (MC) QCD generator MC@NLO (version 3.4) [40, 41], interfaced to HERWIG (version 6.510) [42] for parton showering and hadronization. The CTEQ6M parton distribution functions (PDF) [43, 44] are used to generate events at a top quark mass of $m_t = 172.5$ GeV. We use two samples, one including spin correlation effects, and the other without correlation. The generated events are processed through a GEANT3-based simulation of the D0 detector. To simulate effects from additional overlapping $p\bar{p}$ interactions, “zero bias” events taken from collider data with an unbiased trigger basis solely on beam bunch crossings are overlaid on the simulated events. Simulated events are then processed with the same reconstruction program as data.

In the $\ell\ell$ channels, the main sources of background are Drell-Yan production, $q\bar{q} \rightarrow Z/\gamma^* \rightarrow \ell\ell$, diboson WW, WZ, ZZ production, and instrumental background. The instrumental background arises mainly from multijet and ($W \rightarrow \ell\nu$)+jets events, in which one jet in $W+$jets or two jets in multijet events are misidentified as electrons, or where muons or electrons origi-
nating from semileptonic decay of heavy-flavor hadrons appear to be isolated. The instrumental background is determined from data, while the other backgrounds are estimated using MC simulations. For the $\ell+$jets channel, in addition to the Drell-Yan and diboson production, the contribution from $W+$jets production is estimated from MC simulation, but normalized to data. Electroweak single top quark production and $t\bar{t}$ dilepton final states are also considered as background. The Drell-Yan and ($W \rightarrow \ell\nu$)+jets samples are generated with the leading order (LO) matrix element generator ALPGEN (version v2.11) [40], interfaced to PYTHIA [41] (version 6.409, D0 modified tune A [42]) for parton showering and hadronization. Diboson events are generated with PYTHIA. More details about background estimation can be found in Refs. [43, 44]. Table I shows the number of expected events for each background source and for the signal, and the number of selected events in data. The number of the expected $t\bar{t}$ events is normalized to the NLO cross section of $7.45^{+0.48}_{-0.47}$ pb [49]. The observed number of events in the $\ell+$jets channel is higher than the expected, mainly due to an excess in the $\mu+$jets channel. The expected and observed number of events are consistent when the systematic uncertainties, partially correlated between the $\ell+$jets and $\ell\ell$ channels, are taken into account. These uncertainties are of the order of 10%. The most important contributions are the integrated luminosity, $b$-quark jet modeling, uncertainties on the $t\bar{t}$ modeling and uncertainty in the heavy flavor NLO $K$-factors of the $W+$jets background in the $\ell+$jets channel.

\begin{table}[h]

III. MEASUREMENT TECHNIQUE AND RESULTS

Our measurement uses the same matrix element (ME) approach as Refs. [16, 50], adapted to the spin correlation measurement. This method consists of calculating the spin correlation discriminant [51]

\begin{equation}
R(x) = \frac{P_{t\bar{t}}(x, \mathcal{H})}{P_{t\bar{t}}(x, \mathcal{H}) + P_{t\bar{t}}(x, \text{null})},
\end{equation}

where $P_{t\bar{t}}(x, \mathcal{H})$ is a per-event probability for hypothesis $\mathcal{H}$ for the vector of the reconstructed object parameters $x$. Hypothesis $\mathcal{H} = \text{SM}$ assumes the $t\bar{t}$ spin correlation strength predicted by the SM, and $\mathcal{H} = \text{null}$ assumes uncorrelated spins. These probabilities are calculated from the integral

\begin{equation}
P_{t\bar{t}}(x, \mathcal{H}) = \frac{1}{\sigma_{obs}} \int f_{PDF}(q_1)f_{PDF}(q_2) \times (2\pi)^4 d\Phi^6 dq_1 dq_2.
\end{equation}

Here, $q_1$ and $q_2$ represent the respective fractions of proton and antiproton momentum carried by the initial state partons, $f_{PDF}$ represents the parton distribution functions, $s$ is the square of the $pp$ center-of-mass energy, and $y$ refers to partonic final state four-momenta of the particles. The detector transfer functions, $W(x, y)$, correspond to the probability to reconstruct four-momenta of the particles. The detector transfer functions, $W(x, y)$, correspond to the probability to reconstruct four-momenta of the particles.

The distributions in the discriminant $R$ of Eq. (1) are calculated for simulated $t\bar{t}$ events with SM spin correlation and with uncorrelated spins. These and the expected contributions from the background events are used as templates to fit the $R$ distribution in data through a binned maximum-likelihood fit with two free parameters: the $t\bar{t}$ production cross section $\sigma_{t\bar{t}}$, and the measured fraction of events with the SM spin correlation strength, $f$. This fit of the distributions in the $\ell\ell$ and $\ell+$jets channels is performed simultaneously, with the expected num-
The error bars correspond to statistical uncertainties. The lower plot represents the difference between data and simulation with SM spin correlation and without spin correlation. The error bars correspond to statistical uncertainties.

\]

FIG. 1: Distribution of the spin correlation discriminant \( R \) in data and for the MC@NLO \( \bar{t}t \) prediction with background, showing the merged results from \( \ell\ell \) and \( \ell+\text{jets} \) events. The lower plot represents the difference between data and simulation with SM spin correlation and without spin correlation. The error bars correspond to statistical uncertainties.

\[
n_i = \frac{\sigma_{\text{fit}}}{7.45 \text{pb}} (f n_{\text{SM}}^i + (1-f)n_{\text{null}}^i) + n_{\text{background}}^i,
\]

where \( n_{\text{SM}}^i \) and \( n_{\text{null}}^i \) are the number of events in bin \( i \) based on the MC@NLO prediction, with and without spin correlations, and \( n_{\text{background}}^i \) is the expected number of background events in the same bin. We use a non-uniform bin width and require a sufficiently large number of events for each bin in order to avoid bins with zero events, as they could bias the fit result. The exact number of bins and their size were optimized to give the smallest expected statistical uncertainty in the case of the SM spin correlation. We use the same number and widths of the bins for the \( \ell+\text{jets} \) and \( \ell\ell \) channels so as to keep the bin optimization procedure relatively simple. The fit yields \( f = 1.16 \pm 0.21 \) (stat). The \( R \) distribution for the combined \( \ell\ell \) and \( \ell+\text{jets} \) channels is shown in Fig. 1. We estimate the significance of the non-zero spin correlation hypothesis using the Feldman and Cousins frequentist procedure [52], assuming that the parameter \( f \) is in the range \([0, 1]\), even though the measured value obtained in the fit is outside of the range \([0, 1]\).

To translate the \( f \) value to the spin correlation strength in the off-diagonal basis \( O_{\text{off}} \), we must consider the value of the spin correlation strength in the simulation \( O_{\text{MC}} \). We choose to obtain this value in the simulated \( \ell\ell \) samples from the expected value of \( k_1 k_2 O_{\text{MC}} \) for the expression \( f = -3(V_{\text{CM}}) \) [14], where \( V_{\text{CM}} \) is the CM collision energy. The parameters \( k_1 \) and \( k_2 \) are the spin analyzing-power coefficients of the top quark (equal to 1 for leptons at LO in QCD) [53]. With MC@NLO, the value calculated for the parton-level distributions before any selections is found to equal \( O_{\text{MC}} \) [10]. The measured spin correlation strength for \( \ell+\text{jets} \) and \( \ell\ell \) channels is therefore

\[
O_{\text{MC}} \cdot f = 0.89 \pm 0.16 \text{ (stat)}
\]

in agreement with the NLO QCD calculation \( O_{\text{ref}} = 0.80 \pm 0.01 \) [10]. For events in the \( \ell+\text{jets} \) channel, the result is

\[
O_{\ell+\text{jets}} = 1.02 \pm 0.24 \text{ (stat)}
\]

and for \( \ell\ell \) channel the result is

\[
O_{\ell\ell} = 0.80 \pm 0.22 \text{ (stat)}.
\]

We can reinterpret the measured fraction \( f \) as the related measurement of the spin correlation observable \( O_{\text{spin}} = \langle 0_2 \rangle \) [10]. This observable characterizes the distribution in the opening angle, \( \varphi \), between the directions of the two leptons in dilepton events or between the lepton and the up-type quark from the \( W \) decay in \( \ell+\text{jets} \) events, where the directions are defined in the \( t \) and \( \bar{t} \) rest frame:

\[
\frac{1}{\sigma} \frac{d\sigma}{d\cos\varphi} = \frac{1}{2} (1 - k_1 k_2 O_{\text{spin}} \cos \varphi).
\]

The prediction from the MC@NLO simulation is given by the expectation value \( k_1 k_2 O_{\text{MC}} = -3(V_{\text{CM}}) \) at the parton level, without any selections, and found to be \( O_{\text{MC}} = 0.20 \). The value measured from data is therefore

\[
O_{\text{meas}} = O_{\text{spin}} \cdot f = 0.23 \pm 0.04 \text{ (stat)},
\]

consistent with the NLO QCD calculation of \( O_{\text{spin}} = 0.218 \pm 0.002 \) [10].

IV. SYSTEMATIC UNCERTAINTIES

The estimated systematic uncertainties are summarized in Table II. These are obtained by replacing the nominal \( \bar{t}t \) and background results with modified templates, refitting the data and determining the new fraction \( f_\Delta \).

We consider several sources of uncertainties in the modeling of the signal. These include initial-state and final-state radiation, the simulation of hadronization and underlying events, the effects of higher-order corrections, color-reconnection and uncertainty on the top quark mass. The details of the corresponding samples and parameters are discussed in Refs. 1, 2.

For the PDF uncertainty, we change the 20 CTEQ6 eigenvectors independently and add the resulting uncertainties in quadrature. In modeling both the estimated signal and PDF uncertainties, the event samples have different fractional contributions from \( gg \) fusion and
collinear with the quark in the initial state. This makes NLO, contain a singularity when the final state quark is strongly dependent on the $t\bar{t}$ measuring the fraction of events produced via spin correlation measurement thus provides a way of processes at LO, as well as that the cross sections for the higher than LO QCD. The difficulty arises from the fact $f_{gg}$ contribution at NLO is of the order of a few percent [10, 14, 15], and considering that the overall spin correlation strength is $\approx 80\%$, we neglect these smaller contributions, and determine $f_{gg}$ from the relation

$$O = (1 - f_{gg})O_{q\bar{q}} + f_{gg}O_{gg}.$$  

Assuming $O_{q\bar{q}} \approx 1$, the gluon fraction becomes

$$f_{gg} \approx \frac{1 - O}{1 - O_{gg}},$$

where $O$ is the measured value of the total spin correlation strength, and $O_{gg}$ is the SM value of the spin correlation strength for $gg$ events.

The NLO calculation in the off-diagonal basis using the CT10 PDF yields $O_{gg} = -0.36 \pm 0.02$ [10, 14, 15]. The systematic uncertainty on the observable $O$ can be translated to the uncertainty on the gluon fraction that includes an additional contribution from the theoretical uncertainty on $O_{gg}$. In the absence of non-SM contributions, the fraction of $t\bar{t}$ events produced through gluon fusion becomes

$$f_{gg} = 0.08 \pm 0.12 \text{(stat)} \pm 0.11 \text{(syst)} = 0.08 \pm 0.16 \text{(stat+syst)},$$

in agreement with the NLO prediction of $f_{gg} = 0.135$ [10, 14, 15].

VI. SUMMARY

We have presented an updated measurement of $t\bar{t}$ spin correlations with the D0 detector for an integrated luminosity of 9.7 $fb^{-1}$. The result of the measurement of the strength of the $t\bar{t}$ spin correlation in the off-diagonal basis is

$$O_{off} = 0.89 \pm 0.16 \text{ (stat) } \pm 0.15 \text{ (syst)} = 0.89 \pm 0.22 \text{ (stat+syst)}.$$

This result is in agreement with the NLO QCD calculation $O_{off} = 0.80^{+0.03}_{-0.02}$ [10] and supersedes that reported in Ref. [16]. Using the Feldman and Cousins approach for interval setting [52], and assuming uncorrelated $t\bar{t}$ spins, we estimate a probability (p-value) of $2.5 \times 10^{-5}$ for obtaining a spin correlation larger than the observed value. This corresponds to evidence for spin correlation in $t\bar{t}$ events at a significance of 4.2 standard deviations.

In the absence of non-SM contributions, we use the spin correlation strength measurement to constrain the fraction of events produced through gluon fusion at NLO QCD and obtain

$$f_{gg} = 0.08 \pm 0.16 \text{ (stat + syst)}.$$

in good agreement with SM prediction.
