Received 23 February 2015 / Accepted 15 December 2015

ABSTRACT

We present the most significant measurement of the cosmic microwave background (CMB) lensing potential to date (at a level of 40σ), using temperature and polarization data from the Planck 2015 full-mission release. Using a polarization-only estimator, we detect lensing at a significance of 5σ. We cross-check the accuracy of our measurement using the wide frequency coverage and complementarity of the temperature and polarization measurements. Public products based on this measurement include an estimate of the lensing potential over approximately 70% of the sky, an estimate of the lensing potential power spectrum in bandpowers for the multipole range 40 ≤ ℓ ≤ 400, and an associated likelihood for cosmological parameter constraints. We find good agreement between our measurement of the lensing potential power spectrum and that found in the ACTDM model that best fits the Planck temperature and polarization power spectra. Using the lensing likelihood alone we obtain a percent-level measurement of the parameter combination σ8Ω2 = 0.591 ± 0.021. We combine our determination of the lensing potential with the E-mode polarization, also measured by Planck, to generate an estimate of the lensing B-mode. We show that this result is consistent with standard inflation models, and that the B-mode estimate is correlated with the B-modes observed directly by Planck at the expected level and with a statistical significance of 10σ, confirming Planck’s sensitivity to this known sky signal. We also correlate our lensing potential estimate with the large-scale temperature anisotropies, detecting a cross-correlation at the 3σ level, as expected because of dark energy in the concordance ACTDM model.

Key words. gravitational lensing; weak: cosmological parameters – cosmic microwave background radiation – large-scale structure of Universe – cosmology: observations

1. Introduction

The cosmic microwave background (CMB) gives us a direct measurement of the early Universe when it first became transparent to radiation just 370 000 years after the Big Bang. It contains distinct signatures of the later Universe as well, which were imprinted by the process of gravitational lensing. The CMB photons that we observe today last scattered approximately 14 billion years ago, and have travelled most of the way across the observable Universe to reach us. During their journey, their paths were distorted by the gravitational tug of intervening matter, a subtle effect that may be measured statistically with high angular resolution, low-noise observations of the CMB, such as those provided by Planck. In this paper, we present lensing measurements that are based on the full-mission 2015 data release. We produce the most powerful measurement of CMB lensing to date with a 2.5% constraint on the amplitude of the lensing potential power spectrum (or alternatively, a 40σ detection of lensing effects).

The effect of lensing is to remap the CMB fluctuations, so that the observed anisotropy in direction \( \hat{n} \) in fact is the un lensed, “primordial” anisotropy in the direction \( \hat{n} + \nabla \phi(\hat{n}) \), where \( \phi(\hat{n}) \) is the CMB lensing potential defined by (e.g. Lewis & Challinor 2006)

\[
\phi(\hat{n}) = -2 \int_0^\chi d\chi \frac{f_K(\chi, \eta)}{f_K(\chi_0, \eta_0)} \Psi(\hat{n}; \eta_0 - \chi),
\]

Here, \( \chi \) is conformal distance (with \( \chi_* \approx 14 000 \text{ Mpc} \) denoting the distance to the CMB last-scattering surface). The angular-diameter distance \( f_K(\chi) \) depends on the curvature of the Universe, and is given by

\[
f_K(\chi) = \begin{cases} K^{-1/2} \sin(K^{1/2} \chi) & \text{for } K > 0 \text{ (closed)}, \\ \chi & \text{for } K = 0 \text{ (flat)}, \\ |K|^{-1/2} \sinh(|K|^{1/2} \chi) & \text{for } K < 0 \text{ (open)}. \end{cases}
\]

Finally, \( \Psi(\hat{n}; \eta) \) is the (Weyl) gravitational potential at conformal distance \( \chi \) along the direction \( \hat{n} \) at conformal time \( \eta \) (the conformal time today is denoted as \( \eta_0 \)). The lensing potential is an integrated measure of the mass distribution back to the last-scattering surface. The power spectrum of the lensing potential probes the matter power spectrum, which is sensitive to “late-time” parameters that modify the growth of structure such as neutrino mass (Smith et al. 2009). The amplitude of lensing effects is also a sensitive probe of geometrical parameters, such as the curvature of the Universe.

The lens-induced remapping imparts distinctive statistical signatures onto the observed CMB fluctuations, which can be mined for cosmological information in a process known as lens reconstruction (Okamoto & Hu 2003). The past several years have been seen dramatic improvements in CMB lensing measurements, moving from first detections in cross-correlation (Smith et al. 2007; Hirata et al. 2008) to cosmologically useful measurements of the lensing potential power spectrum (Das et al. 2011; van Engelen et al. 2012; Planck Collaboration XVII 2014). Recently, ground-based experiments have been able to detect the effects of lensing in polarization data as well (Hanson et al. 2013; POLARBEAR Collaboration 2014a,b; van Engelen et al. 2015).

The results in this paper extend our earlier results in Planck Collaboration XVII (2014). These were based on the March 2013 Planck1 nominal-mission data release, which contains approximately 15 months of temperature data alone. The additional information in the full-mission dataset, with 30 months of Planck HFI temperature and polarization data (Planck Collaboration VII 2016; Planck Collaboration VIII 2016), allows us to improve our reconstruction noise levels by roughly a factor of two. Approximately half of this improvement comes from lower noise levels in temperature, and the other half from inclusion of polarization data. The improved lensing map is included as part of the Planck 2015 public data release (Planck Collaboration I 2016), as well as an estimate of the lensing potential power spectrum and associated likelihoods. In this paper we describe the creation of these products, as well as first science results based on them. We highlight the following science results.

- We detect lensing B-modes in the Planck data at a significance of 10σ, using both a cross-correlation approach with the cosmic infrared background (CIB) as a tracer of the lensing potential, as well as a CMB-only approach using the TTEE bispectrum. This provides an important confirmation that Planck is sensitive to this known source of B-modes on intermediate and small scales.
- We make an improved measurement of the 3-point function (bispectrum) that is induced in the CMB by the correlation between lensing and the integrated Sachs-Wolfe (ISW) effect, the latter being sourced by late-time acceleration. The lensing-ISW bispectrum is now detected at the 3σ level.
- Using only lensing information (along with well-motivated priors), we constrain the parameter combination \( \sigma_8 \Omega_m^{25} \) to roughly 3%.

The organization of this paper is as follows. In Sect. 2 we give a summary of our analysis pipeline for the full-mission data. Our analysis is very similar to that presented in Planck Collaboration XVII (2014), with straightforward extensions to polarization data, as well as a few additional improvements, and so we have deferred most technical details to appendices. In Sect. 3 we present our main results, including the lensing potential map, bandpower estimates of the lensing potential power spectrum, and implications for cosmological parameters. In Sect. 4 we present a suite of consistency and null tests to verify our bandpower estimates, and in Sect. 5 we conclude. A series of appendices provide more technical details of our analysis pipeline, modeling of the CIB, and dependence of the lensing power spectrum on \( \Lambda \)CDM parameters.

2. Data and methodology

Here we give a brief overview of the procedure that we use to measure the CMB lensing potential and its power spectrum from the Planck maps. We defer the detailed technical aspects of our pipeline to Appendix A.

Our main results are based on a foreground-cleaned map of the CMB synthesized from the raw Planck 2015 full-mission frequency maps using the SMICA code (Planck Collaboration IX 2016). This foreground-cleaned map combines all nine frequency bands from 30 GHz to 857 GHz with scale-dependent

---

1 Planck (http://www.esa.int/Planck) is a project of the European Space Agency (ESA) with instruments provided by two scientific consortia funded by ESA member states and led by Principal Investigators from France and Italy, telescope reflectors provided through a collaboration between ESA and a scientific consortium led and funded by Denmark, and additional contributions from NASA (USA).
Fig. 1. Lens reconstruction noise levels $N_\ell$ for the TT, TE, EE, EB, and TB estimators applied to the SMICA full-mission CMB map. The noise level for their minimum-variance combination (MV) is also shown. The fiducial $\Lambda$CDM theory power spectrum $C_{\ell}^{\phi\phi}$ used in our Monte Carlo simulations is plotted as the black solid line.

coefficients chosen to provide unit response to the CMB with minimal variance; for more details see Planck Collaboration IX (2016)\(^2\). On the small scales where lensing effects are most important (multipoles above $\ell = 1000$), most of the CMB information in the foreground-cleaned maps originates with the 143 GHz and 217 GHz channel data. These channels have beams that are approximately Gaussian with full-width-at-half-maximum (FWHM) parameters of $7^\prime$ and $5^\prime$, respectively. Their noise is approximately white for $1000 \leq \ell \leq 3000$, with levels of 30 $\mu$K arcmin (60 $\mu$K arcmin) in temperature (polarization) at 143 GHz, and 40 $\mu$K arcmin (95 $\mu$K arcmin) at 217 GHz.

We reconstruct the CMB lensing potential using quadratic estimators that exploit the statistical anisotropy induced by lensing, following Okamoto & Hu (2003). Neglecting the lensing of primordial B-modes there are five possible estimators, denoted by $\hat{\phi}^{TT}$, $\hat{\phi}^{TE}$, $\hat{\phi}^{EE}$, $\hat{\phi}^{EB}$, and $\hat{\phi}^{TB}$, which are based on various correlations of the CMB temperature ($T$) and polarization ($E$ and $B$). In addition, we can form a minimum-variance estimator that combines all five estimators, which we denote as $\hat{\phi}^{MV}$. In Fig. 1 we plot the lens reconstruction noise levels for these estimators. The most powerful estimator is $TT$, although the $TE$ and $EE$ estimators are also useful on large angular scales.

The quadratic lensing estimators take inverse-variance filtered CMB multipoles as input. We obtain these using a filter that masks the Galaxy and point sources, and also bandpass filters the data in harmonic space to $100 \leq \ell \leq 2048$. For our baseline analysis, we start with the masks used in the analysis of Planck Collaboration XVII (2014), with a Galaxy mask that removes 30.2% of the sky and a point-source mask that removes an additional 0.7% of the sky. This removes the brightest Sunyaev-Zel’dovich (SZ) clusters as described in Planck Collaboration XVII (2014); contamination of the lensing reconstruction from residual unresolved SZ is expected to be at the percent level for Planck (van Engelen et al. 2014), even without component

\[3\] this residual signal, and that from unresolved point-sources, is further reduced by a correction that we make to the power spectrum of the reconstructed lensing potential (see Appendix A.3). Finally, we apply SMICA-specific temperature and polarization masks described in Planck Collaboration IX (2016). Combining all three sets of masks leaves a total of 67.3% of the sky for analysis.

We estimate the power spectrum of the lensing potential $C_{\ell}^{\phi\phi}$ using the auto- and cross-spectra of the quadratic lensing estimators\(^3\). These spectra probe the 4-point function of the lensed CMB, specifically the connected (trispectrum) part of the 4-point function that is sourced by lensing. They also contain contributions from the disconnected part of the 4-point function (which is non-zero even in the absence of lensing effects). We estimate this contribution and subtract it, as well as several other smaller bias terms, obtaining an estimate $\hat{C}_{\ell}^{\phi\phi}$ of the power spectrum. This procedure is discussed in Appendix A.3. For cosmological parameter constraints, we use a Gaussian log-likelihood in bandpowers of the estimated lensing power spectrum, given by

\[-2 \log L_{\phi} = \hat{B}_{i j}^{\ell} (\hat{C}_{\ell}^{\phi\phi} - C_{\ell}^{\phi\phi}) \Sigma^{-1} \hat{B}_{i j}^{\ell} (\hat{C}_{\ell}^{\phi\phi} - C_{\ell}^{\phi\phi}).\]

Here, bins are indexed by $i$ and $j$; $\hat{B}_{i j}^{\ell}$ is the bandpower binning function for the $i$th bin, and $\Sigma$ is a covariance matrix for the bin estimates. Paired upper/lower indices are summed over. The $C_{\ell}^{\phi\phi}$ is the theoretical expectation value of the estimated $\hat{C}_{\ell}^{\phi\phi}$ for the set of cosmological and nuisance parameters under consideration. This generally differs from the theory spectrum $C_{\ell}^{\phi\phi}$ at the same cosmological parameters due to the way that our power spectrum estimates are normalized, and corrected for additional trispectrum couplings, with a fiducial model. Both the binning function and $C_{\ell}^{\phi\phi}$ are discussed in Appendix C. The binning function is chosen to have unit response to a fiducial theory spectrum $C_{\ell}^{\phi\phi,fid}$, and so we denote

\[\hat{A}_{\ell}^{\phi} = \hat{B}_{i j}^{\ell} \hat{C}_{\ell}^{\phi\phi}\]

as the amplitude of the power spectrum for a particular bin relative to the fiducial expectation (with $\hat{A} = 1$ for $C_{\ell}^{\phi\phi} = C_{\ell}^{\phi\phi,fid}$).

To characterize the variance of our lensing potential estimates, as well as to estimate several bias terms, we use simulated Planck maps. These are based on the Full Focal Plane 8 (FFP8) Monte Carlo simulation set described in Planck Collaboration XII (2016). As discussed there, the Planck maps were effectively renormalized by approximately 2–3% in power in the time between the generation of FFP8 and the final Planck full-mission maps. To account for this, we rescale the CMB component of the simulations by a factor of 1.0134 before analysis. The FFP8 simulations do not include contributions from residual foregrounds (Galactic dust, as well as unmasked point sources), and also underestimate the noise power spectra by several percent at high-$\ell$.

\[2\] We use a slightly earlier version of SMICA maps than those in the public release. They differ by pixel-smoothing and missing-pixel mask, however this has no significant effect on the results.

\[3\] We mask clusters with $S/N \geq 5$ in the Planck cluster catalogue that accompanied the 2013 release (PSZ1; Planck Collaboration XXIX 2014). The mass limit is redshift dependent, with a high-redshift limit at 80% completeness of $M_{500} \approx 6 \times 10^{14} M_\odot$. If we conservatively adopt this mass limit (we certainly mask low-redshift clusters to lower masses), the results of van Engelen et al. (2014) suggest that the SZ trispectrum at 143 GHz gives a positive bias of at most a few percent in the reconstructed lensing power spectrum for multipoles $\ell < 2000$, while the lensing-SZ-SZ bispectrum gives a negative bias of similar size. The SZ signal is much smaller in the 217 GHz temperature data, which is around the null of the (thermal) SZ effect.

\[4\] In this paper, we use multipole indices $LM$ for the lens reconstruction, reserving multipole indices $im$ for the CMB fields.
We account for this missing power simply by adding coloured Gaussian noise to the simulations to make their $TT$, $EE$, and $BB$ power spectra agree with the data. This approach implicitly assumes that any non-Gaussianity of these residual components does not couple significantly to our lensing estimates. We perform consistency tests in Sect. 4 to check the validity of these assumptions.

Throughout this paper we use a spatially-flat fiducial cosmology with baryon density given by $\omega_c = \Omega_c h^2 = 0.0222$, cold dark matter (CDM) density $\omega_c = \Omega_c h^2 = 0.1203$, neutrino energy density $\omega_\nu = \Omega_\nu h^2 = 0.00064$ (corresponding to two massless neutrinos and one massive with mass $0.06 eV$), Hubble constant $H_0 = 100 h \text{ km s}^{-1} \text{ Mpc}^{-1}$ with $h = 0.6712$, spectral index of the power spectrum of the primordial curvature perturbation $n_s = 0.96$, amplitude of the primordial power spectrum (at $k = 0.05 \text{ Mpc}^{-1}$) $A_s = 2.09 \times 10^{-9}$, and Thomson optical depth through reionization $\tau = 0.065$. These cosmological parameters also form the basis for the FFP8 Monte Carlo simulation set. In addition to rescaling the FFP8 maps as already discussed, we have also adjusted the power spectra of the fiducial model by rescaling the CMB temperature and polarization spectra by a factor of 1.0134, and the temperature-lensing cross-correlation $C^{\ell \phi}_{TT}$ by 1.0134. We have not applied any scaling to the fiducial lensing power spectrum. Our reconstruction methodology (in particular, the renormalization corrections, addition of foreground power, and realization-dependent bias corrections that we apply, discussed in Appendix C) renders the cosmological interpretation of our lensing estimates insensitive to errors in the fiducial model power spectra and simulations.

3. Results

In this section, we provide a summary of the first science results obtained with the minimum-variance lens reconstruction from the Planck full-mission data. The lensing potential map is presented in Sect. 3.1, and this is combined in Sect. 3.2 with the $E$-mode polarization measured by Planck to obtain a map of the expected $B$-mode polarization due to lensing. We further show that this is correlated with the $B$-modes measured by Planck at the expected level. In Sect. 3.3, we cross-correlate the reconstructed lensing potential with the large-angle temperature anisotropies to measure the $C^{\ell \phi}_{TT}$ correlation sourced by the ISW effect. Finally, the power spectrum of the lensing potential is presented in Sect. 3.4. We use the associated likelihood alone, and in combination with that constructed from the Planck temperature and polarization power spectra (Planck Collaboration XI 2016), to constrain cosmological parameters in Sect. 3.5.

3.1. Lensing potential

In Fig. 2 we plot the Wiener-filtered minimum-variance lensing estimate, given by

$$\hat{\phi}_{LM}^{\text{WF}} = \frac{C^{\ell \phi}_{L \text{ fid}}}{C^{\ell \phi}_{L \text{ fid}} + N^{\delta \delta}_{L \text{ fid}}} \hat{\phi}_{LM}^{\text{MV}},$$

(5)

where $C^{\ell \phi}_{L \text{ fid}}$ is the lensing potential power spectrum in our fiducial model and $N^{\delta \delta}_{L \text{ fid}}$ is the noise power spectrum of the reconstruction. As we shall discuss in Sect. 4.5, the lensing potential estimate is unstable for $L < 8$, and so we have excluded those modes for all analyses in this paper, as well as in the MV lensing map.

As a visual illustration of the signal-to-noise level in the lensing potential estimate, in Fig. 3 we plot a simulation of the MV reconstruction, as well as the input $\phi$ realization used. The reconstruction and input are clearly correlated, although the reconstruction has considerable additional power due to noise. As can be seen in Fig. 1, even the MV reconstruction only has $S/N \approx 1$ for a few modes around $L \approx 50$.

The MV lensing estimate in Fig. 2 forms the basis for a public lensing map that we provide to the community (Planck Collaboration I 2016). The raw lensing potential estimate has a very red power spectrum, with most of its power on large angular scales. This can cause leakage issues when cutting the map (for example to cross-correlate with an additional mass tracer over a small portion of the sky). The lensing convergence $k$ defined by

$$k_{LM} = \frac{L(L+1)}{2} \phi_{LM},$$

(6)
has a much whiter power spectrum, particularly on large angular scales. The reconstruction noise on $\kappa$ is approximately white as well (Bucher et al. 2012). For this reason, we provide a map of the estimated lensing convergence $\kappa$ rather than the lensing potential $\phi$.

### 3.2. Lensing B-mode power spectrum

The odd-parity $B$-mode component of the CMB polarization is of great importance for early-universe cosmology. At first order in perturbation theory it is not sourced by the scalar fluctuations that dominate the temperature and polarization anisotropies, and so the observation of primordial $B$-modes can be used as a uniquely powerful probe of tensor (gravitational wave) or vector perturbations in the early Universe. A detection of $B$-mode fluctuations on degree angular scales, where the signal from gravitational waves is expected to peak, has recently been reported at 150 GHz by the BICEP2 collaboration (Ade et al. 2014). Following the joint analysis of BICEP2 and Keck Array data (also at 150 GHz) and the Planck polarization data, primarily at 353 GHz (BICEP2/Keck Array and Planck Collaborations 2015), it is now understood that the $B$-mode signal detected by BICEP2 is dominated by Galactic dust emission. The joint analysis gives no statistically-significant evidence for primordial gravitational waves, and establishes a 95% upper limit $r_{0.05} < 0.12$. This still represents an important milestone for $B$-mode measurements, since the direct constraint from the $B$-mode power spectrum is now as constraining as indirect, and model-dependent, constraints from the $TT$ spectrum (Planck Collaboration XIII 2016).

In addition to primordial sources, the effect of gravitational lensing also generates $B$-mode polarization. The displacement of lensing mixes $E$-mode polarization into $B$-mode as (Smith et al. 2009)

$$B^\text{lens}_{E\ell m} = (-1)^m \sum_L \sum_{m_L} \left( \ell_E \ell_B m_E - m_B \right) W^{\phi_B}_{\ell \ell_L m} E_{\ell_L m_L} \phi_{LM},$$

where $W^{\phi_B}_{\ell \ell_L m}$ is a weight function and the bracketed term is a Wigner-3j symbol. On scales $\ell_B \lesssim 1000$ the lensing $B$-mode power spectrum resembles that of white noise, with a level of about $5 \mu K$ arcmin. This lensing power acts as a potential source of confusion for the measurement of primordial $B$-modes, which can be estimated and ultimately removed in a process of delensing. Given an estimate for the lensing potential $\phi$ and the $E$-mode polarization measured by Planck we can synthesize a lensed $B$-mode map for this purpose using Eq. (7). The $5 \mu K$ arcmin level of the lensing $B$-mode power spectrum is an order of magnitude lower than the Planck 2015 noise levels, and so delensing does not significantly improve our $B$-mode measurements; however, the cross-correlation of the lensing $B$-mode template with the observed $B$-mode sky provides a useful check on the ability of Planck to measure this known source of $B$-modes.

We show the results of such a cross-correlation in Fig. 4, finding good agreement with the expected lensing $B$-mode power spectrum. In addition to our fiducial MV lensing potential estimate, which uses both temperature and polarization data, we have also estimated the lensing $B$-mode power spectrum using the $TT$-only lensing estimator to measure $\phi$, as well as the CIB fluctuations measured by the $545 \text{GHz Planck}$ channel.

The observed $B$-mode signal is now understood to be $5\sigma$ significant, with a level of about $5 \mu K$ arcmin. This lensing power acts as a potential source of confusion for the measurement of primordial $B$-modes, which can be estimated and ultimately removed in a process of delensing. Given an estimate for the lensing potential $\phi$ and the $E$-mode polarization measured by Planck we can synthesize a lensed $B$-mode map for this purpose using Eq. (7). The $5 \mu K$ arcmin level of the lensing $B$-mode power spectrum is an order of magnitude lower than the Planck 2015 noise levels, and so delensing does not significantly improve our $B$-mode measurements; however, the cross-correlation of the lensing $B$-mode template with the observed $B$-mode sky provides a useful check on the ability of Planck to measure this known source of $B$-modes.

We see good agreement in all cases with the expected power; constraining the overall amplitude of the lensing $B$-mode power spectrum $A^B$ (relative to the predicted spectrum in our fiducial model) for a large bin from $8 \leq \ell_B \leq 2048$ we measure amplitudes of

$$A^B_{8-2048} = 0.93 \pm 0.08 \ (\phi^{\text{MV}}),$$
$$A^B_{8-2048} = 0.95 \pm 0.09 \ (\phi^{TT}),$$
$$A^B_{8-2048} = 0.93 \pm 0.10 \ (\text{CIB})$$

for the three estimates, each corresponding to a roughly $10\sigma$ detection of lensing $B$-mode power in the Planck data. The shape of the cross-correlation is also in good agreement with expectation. Taking the bins in Fig. 4 as independent, forming a $\chi^2$ relative to the theory model and comparing to the distribution from simulations we obtain probability-to-exceed (PTE) values of 48%, 71%, and 78% using the MV, $TT$, and CIB lensing estimates, respectively.

### 3.3. Lensing-ISW bispectrum

As photons travel towards us from the last scattering surface, they are not only deflected by gravitational lensing, they also receive net red/blueshifts from gravitational potentials that evolve if they are crossed at late times. This phenomenon, known as the integrated Sachs-Wolfe (ISW) effect, is believed to generate anisotropies in the observed CMB temperature on large ($\ell \lesssim 100$) angular scales. It is of particular interest because the decay of gravitational potentials, which produces the ISW effect, does not occur during matter domination, but only at redshifts $z \lesssim 2$ when dark energy becomes dynamically important. The ISW effect can be detected statistically by cross-correlating the observed temperature anisotropies with a tracer of structure at these redshifts. Here we use the lensing potential, which is well-matched to the ISW effect (Hu 2002). Current Planck results...
incorporating additional external tracers of large-scale structure are summarized in Planck Collaboration XXI (2016).

In Fig. 5 we plot the cross-correlation $C_{L}^{T\phi}$ between the MV lens reconstruction and the CMB temperature. This cross-correlation probes the bispectrum, or three-point correlation function of the CMB, which is due to the correlation of the lensing and ISW effects. The measurement is noisy, due to a combination of noise in the lens reconstruction and cosmic variance in the temperature (which ultimately limits the detection of the lensing-ISW bispectrum to about 3σ significance).

To determine the overall detection significance for the cross-correlation, we use the minimum-variance bispectrum estimator

$$\hat{A}_{L}^{T\phi} = \frac{1}{N^{T\phi}} \sum_{LM} c_{L}^{T\phi, \text{fid}} \phi_{LM} \frac{T_{L}^{\text{fid}}}{C_{L}^{T\phi, \text{fid}} + N_{L}^{T\phi}}$$

where $N^{T\phi}$ is a normalization determined from simulations. For the MV lens reconstruction, using $8 \leq L \leq 100$ we measure an amplitude

$$\hat{A}_{L}^{T\phi} = 0.90 \pm 0.28 \quad (\text{MV}),$$

which is consistent with the theoretical expectation of unity and non-zero at just over 3σ. Using the $TT$-only lensing estimate rather than the MV lensing estimate in the cross-correlation, we obtain

$$\hat{A}_{L}^{T\phi} = 0.68 \pm 0.32 \quad (TT).$$

Using simulations, we measure an rms difference between the $TT$ and MV bispectrum amplitudes of 0.18 (roughly equal to the quadratic difference of their error bars, which is $\sqrt{0.32^2 - 0.28^2} = 0.15$). Therefore the difference of amplitudes, $\hat{A}_{L}^{T\phi} = 0.22$, is compatible with the expected scatter.

We find $N^{T\phi}$ is within 4% of the analytical expectation

$$N^{T\phi} = \sum_{L} (2L+1) \left( c_{L}^{T\phi, \text{fid}} \right)^2 \frac{1}{C_{L}^{T\phi, \text{fid}} + N_{L}^{T\phi}}.$$

In Planck Collaboration XVII (2014), using the $TT$ lensing estimator on the multipole range $10 \leq L \leq 100$ we measured a somewhat higher value for the lensing-ISW bispectrum amplitude $\hat{A}_{L=10-100}^{T\phi} = 0.85 \pm 0.35$. We expect the difference with respect to the 2015 $TT$ measurement to have standard deviation of approximately $\sqrt{0.35^2 - 0.32^2} = 0.14$, and so the observed difference of $0.85 - 0.68 = 0.17$ is reasonable.

### 3.4. Lensing potential power spectrum

In Fig. 6 we plot our estimate of the lensing potential power spectrum obtained from the MV reconstruction, as well as several earlier measurements. We see good agreement with the shape in the fiducial model, as well as earlier measurements (detailed comparisons with the 2013 spectrum are given later in this section). In Sect. 4 we perform a suite of internal consistency and null tests to check the robustness of our lensing spectrum to different analysis and data choices.

We estimate the lensing potential power spectrum in bandpowers for two sets of bins: a “conservative” set of eight uniformly-spaced bins with $\Delta L = 45$ in the range $40 \leq L \leq 400$; and an “aggressive” set of 18 bins that are uniformly spaced in $L^{10}$ over the multipole range $8 \leq L \leq 2048$. The conservative bins cover a multipole range where the estimator signal-to-noise is greatest. They were used for the Planck 2013 lensing likelihood described in Planck Collaboration XVII (2014). The aggressive bins provide good sensitivity to the shape of the lensing power on both large and small scales, however they are more easily biased by errors in the mean-field corrections (which are large at $L < 40$) and the disconnected noise bias corrections (at $L > 400$). Results for the bandpower amplitudes $\hat{A}_{L}^{T\phi}$ defined in Eq. (4), are given in Table 1 for both sets of multipole bins.

Nearly all of the internal consistency tests that we present in Sect. 4 are passed at an acceptable level. There is, however, mild evidence for a correlated feature in the curl-mode null-test, centred around $L \approx 500$. The $L$ range covered by this feature includes $638 \leq L \leq 762$, for which the (gradient) lensing reconstruction bandpower is $3.6\sigma$ low compared to the predicted power of the fiducial model. In tests of the sensitivity of parameter constraints to lensing multipole range, described later in Sect. 3.5.4, we find that for parameters of around $1\sigma$ in going from the conservative to aggressive range, with negligible improvement in the parameter uncertainty. Around half of these shifts come from the outlier noted above. For this reason, we adopt the conservative multipole range as our baseline here, and in other Planck 2015 papers, when quoting constraints on cosmological parameters. However, where we quote constraints on amplitude parameters in this paper, we generally give these for both the aggressive and conservative binning.

We estimate the overall lensing amplitude (following Eq. 4) relative to our fiducial theoretical model, for a single bin over both the aggressive and conservative multipole ranges we find

$$\hat{A}_{L}^{T\phi, \text{MV}} = 0.987 \pm 0.025, \quad (11a)$$

$$\hat{A}_{L}^{T\phi, \text{MV}} = 0.983 \pm 0.025, \quad (11b)$$

We find $\hat{A}_{L}^{T\phi, \text{MV}}$ is consistent with the theoretical expectation at $L \leq 400$.
Fig. 6. Planck 2015 full-mission MV lensing potential power spectrum measurement, as well as earlier measurements using the Planck 2013 nominal-mission temperature data (Planck Collaboration XVII 2014), the South Pole Telescope (SPT, van Engelen et al. 2012), and the Atacama Cosmology Telescope (ACT, Das et al. 2014). The fiducial CDM theory power spectrum based on the parameters given in Sect. 2 is plotted as the black solid line.

These measurements of the amplitude of the lensing power spectrum both have precision of 2.5%, and are non-zero at 40π. Given the measured amplitude, it is clear that our overall lensing amplitude estimate is consistent with our fiducial CDM model (which has Λ = 1). The shape of our measurement is also in reasonable agreement with the fiducial model. Marginalizing over an overall amplitude parameter, for the 19 bins plotted in Fig. 6 we obtain a χ² with respect to our fiducial model of 28 (with N_{dof} = 18), with a corresponding PTE of 6%. A large portion of this χ² is driven by the outlier bandpower with 638 ≤ L ≤ 762. Removing this bandpower gives a χ² of 16.5 (N_{dof} = 17), with a PTE of 49%. For the more conservative multipole range 40 ≤ L ≤ 400, using eight linear bins we obtain χ² of 8.9 (N_{dof} = 7), with a PTE of 26%.

Finally, we note that the lensing bandpowers measured here are in good agreement with the Planck 2013 results (Planck Collaboration XVII 2014). The only clear visual difference between the two measurements in Fig. 6 is for the L = 40–65 bin, where the 2013 bandpower is significantly higher than the current measurement. As previously discussed in Planck Collaboration XVII (2014), this bin amplitude was sensitive to the choice of foreground cleaning, and decreased when using a component-separated map for the reconstruction (as is done here), and so this difference is expected. To compare measurements in further detail, we calculate a χ² for the difference between our 2013 and 2015 MV lensing bandpower estimates assuming a diagonal covariance as

\[ \chi^2_{2013-2015} = \sum_{b} \frac{(C_L^{\phi\phi}_{2013} - C_L^{\phi\phi}_{2015})^2}{\text{Var}(C_L^{\phi\phi}_{2013}) - \text{Var}(C_L^{\phi\phi}_{2015})}, \]

where L_b indexes the bandpower bins. We approximate the variance of the differences of the bandpowers as the difference of the variances in forming this χ². Using the conservative bins for 40 ≤ L ≤ 400, which were used for the 2013 lensing likelihood, we obtain a value of \( \chi^2_{2013-2015} = 10.8 \) (N_{dof} = 8), with a corresponding PTE of 22%. The 2013 result is temperature only; if we compare it directly to the 2015 TT lensing bandpowers, we obtain a value of \( \chi^2 = 7.2 \) (N_{dof} = 8, PTE = 52%). We note that some care should be taken when comparing the measured lensing amplitudes between 2013 and 2015, because the fiducial spectra against which they are measured differ significantly. In 2013, for example, we measured \( \hat{A}_L^{\phi\phi} \geq 40 \) = 0.943 ± 0.040. However, this was measured with respect to a fiducial \( C^\phi \) that is between 6% and 7% higher than the one used here in this multipole range. Renormalizing the 2013 measurements to determine the amplitude for the 2015 fiducial cosmology, we obtain 1.005 ± 0.043, which can be compared directly to the measurement of \( \hat{A}_L^{\phi\phi, MV} \geq 40 \) = 0.987 ± 0.025 for 2015. It is interesting to note that there is a 2% difference in power between the Planck 2013 and 2015 maps from HFI due to a change in the calibration, as well as an improved beam model (Planck Collaboration VII 2016). This shift does not couple to the lensing reconstruction; lensing is a geometric effect, and so an overall change in the calibration does not affect the lens reconstruction procedure, provided that a consistent power spectrum is used to analyse the maps, as is done here.

3.5. Likelihoods and cosmological parameter constraints

In this section we discuss cosmological implications of the Planck lensing potential power spectrum estimate. We use a Gaussian likelihood in the measured bandpowers, with corrections to account for errors in the fiducial CMB power spectra that are used to normalize and debias the lensing estimates. This procedure is described in more detail in Appendix C.

Notes. The $\hat{A}^p$ values are dimensionless, with $A^p = 1$ for a measured spectrum equal to the lensing potential power spectrum of our fiducial cosmology (described in Sect. 2). The final column lists bandpower estimates, averaged within each bin.

In the following subsections, we discuss the information that can be gleaned from the lensing potential power spectrum alone, or in conjunction with the Planck 2015 CMB power spectrum likelihood. Some of the results in this section summarize the parts of Planck Collaboration XIII (2016) that are directly related to lensing.

#### 3.5.1. Constraints from CMB lensing alone

The measurement of the lensing power spectrum is obtained from the 4-point function of the observed CMB anisotropies, and hence depends in general on both the lensing and CMB power spectra (see Appendix C). However the latter are now well measured by Planck, and there is only a weak dependence on cosmological parameters given the observed spectra (mainly via different cosmological models changing foreground parameters, and hence the amplitude of underlying CMB power spectra). In this section we fix the CMB power spectra to a $\Lambda$CDM Planck TT+lowP best fit (i.e. using TT on all scales and low-$\ell$ polarization), and consider the conditional probability of different cosmological parameters given only the lensing reconstruction power spectrum.

To avoid marginalizing over very unrealistic values of poorly constrained parameters, we adopt several well-motivated priors when considering constraints from lensing alone.

- The optical depth to reionization is fixed to $\tau = 0.07$, because lensing deflections are independent of reionization (and scattering and subsequent lensing from sources at reionization is negligible).
- The baryon density is given a Gaussian 1σ prior $\Omega_m h^2 = 0.0223 \pm 0.0009$, as measured independently from big bang nucleosynthesis models combined with quasar absorption line observations (Pettini & Cooke 2012).
- The scalar spectral index is given a broad prior $n_s = 0.96 \pm 0.02$; results are only weakly sensitive to this choice, within plausible bounds.
- A top-hat prior is used for the reduced Hubble constant, $0.4 < h < 1$. This limits the extent of the parameter degeneracy, but does not affect the results over the region of interest for joint constraints.

In addition to the priors above, we adopt the same sampling priors and methodology as Planck Collaboration XIII (2016)\(^5\), using CosmoMC and camb for sampling and theoretical predictions (Lewis & Bridle 2002; Lewis et al. 2000). In the $\Lambda$CDM model, as well as $\Omega_M h^2$ and $n_s$, we sample $A_s$, $\Omega_b h^2$, and the (approximate) acoustic-scale parameter $\theta_{\text{MC}}$. Alternatively, we can think of our lensing-only results as constraining the sub-space of $\Omega_m$, $H_0$, and $\sigma_8$. Figure 7 shows the corresponding constraints from CMB lensing, along with tighter constraints from combining with additional external baryon acoustic oscillation (BAO) data, compared to the constraints from the Planck

---

\(^5\) For example, we split the neutrino component into approximately two massless neutrinos and one with $\sum m_\nu = 0.06$ eV, by default.
CMB power spectra. The contours overlap in a region of acceptable Hubble constant values, and hence are compatible. To show the multi-dimensional overlap region more clearly, the red contours show the lensing constraint when restricted to a reduced-dimensionality space with $\theta_{MC}$ fixed to the value accurately measured by the CMB power spectra; the intersection of the red and black contours gives a clearer visual indication of the consistency region in the $\Omega_m - \sigma_8$ plane.

The lensing-only constraint defines a band in the $\Omega_m - \sigma_8$ plane, with the well-constrained direction corresponding approximately to the constraint

$$\sigma_8 \Omega_m^{0.25} = 0.591 \pm 0.021 \quad \text{(lensing only; 68%).}$$

This parameter combination is measured with approximately 3.5% precision.

The dependence of the lensing potential power spectrum on the parameters of the $\Lambda$CDM model is discussed in detail in Appendix E; see also Pan et al. (2014). Here, we aim to use simple physical arguments to understand the parameter degeneracies of the lensing-only constraints. In the flat $\Lambda$CDM model, the bulk of the lensing signal comes from high redshift ($z > 0.5$) where the Universe is mostly matter-dominated (so potentials are nearly constant), and from lenses that are still nearly linear. For fixed CMB (monopole) temperature, baryon density, and $n_s$, in the $\Lambda$CDM model the broad shape of the matter power spectrum is determined mostly by one parameter, $k_{eq} \equiv k_{eq} H_{eq} \propto \Omega_m h^2$. The matter power spectrum also scales with the primordial amplitude $A_s$; keeping $A_s$ fixed, but increasing $k_{eq}$, means that the entire spectrum shifts sideways so that lenses of the same typical potential depth $\Psi_{\text{len}}$ become smaller. Theoretical $\Lambda$CDM models that keep $\ell_{eq} \equiv k_{eq} X_s$ fixed will therefore have the same number (proportional to $k_{eq} X_s$) of lenses of each depth along the line of sight, and distant lenses of the same depth will also maintain the same angular correlation on the sky, so that the shape of the spectrum remains roughly constant. There is therefore a shape and amplitude degeneracy where $\ell_{eq} \propto k_{eq} X_s$ constant, up to corrections from sub-dominant changes in the detailed lensing geometry, changes from late-time potential decay once dark energy becomes important, and nonlinear effects. In terms of standard $\Lambda$CDM parameters around the best-fit model, $\ell_{eq} \propto \Omega_m^{0.67} h$, with the power-law dependence on $\Omega_m$ only varying slowly with $\Omega_m$; the constraint $\ell_{eq} \propto \Omega_m^{0.67} h = \text{constant}$ defines the main dependence of $H_0$ on $\Omega_m$ seen in Fig. 7.

The argument above for the parameter dependence of the lensing power spectrum ignores the effect of baryon suppression on the small-scale amplitude of the matter power spectrum (e.g. Eisenstein & Hu 1998). As discussed in Appendix E, this introduces an explicit dependence of the lensing power spectrum on $\Omega_m h^2$. However, since the parameter dependence of $\ell_{eq}$ is close to $(\Omega_m h^2)^{1/2}$, we can still think of $A_s$ and $\ell_{eq}$ as giving the dominant dependence of $C_L^{\phi \phi}$ on parameters.

In practice the shape of $C_L^{\phi \phi}$ is not measured perfectly, and there is also some degeneracy between $A_s$, which directly increases the amplitude, and $\ell_{eq}$, which increases the amplitude via an increase in the number of lenses along the line of sight and indirectly by changing the depth of potential wells of a given size. On small angular scales with $L > \ell_{eq}$, $\Psi_{\text{len}}$ becomes a strong function of scale due to the fall-off in the matter power spectrum for $k > k_{eq}$. For a fixed comoving scale, the amplitude increases if $k_{eq}$ becomes larger since this reduces the amount of decay of the gravitational potential during radiation domination (Pan et al. 2014), and also lessens the impact of baryon suppression. This increases the dependence of $C_L^{\phi \phi}$ on $\ell_{eq}$ beyond the linear scaling from the number of lenses, and on small scales $L^2 C_L^{\phi \phi} \propto A_s^{1+\eta_s}$, where $n_s > 0$ determines the actual $L$-dependence (inherited from the scale dependence of the small-scale matter power spectrum and the effect of baryon suppression). For Planck, the lensing spectrum is best measured at $L \sim 200$: since $n_s$ increases with $L$, making $A_s$ larger and $\ell_{eq}^{1+\eta_s}$ smaller to keep the power constant at $L \sim 200$ leads to an increase in power at lower $L$ and a decrease in power at higher $L$ (see Fig. 8). The lensing amplitude at the peak $L \approx 50$ (and hence the rms deflection angle), is therefore slightly anti-correlated with the amount of small-scale power (as shown by the lensing only constraint in Fig. 9; see discussion below).

The actual three-parameter constraint is close to

$$A_s \left(\Omega_m^{0.67} h\right)^{2.3} \propto A_s \ell_{eq}^{2.3} \propto \text{constant} \pm 3\%,$$

Fig. 8. Lensing potential power spectra in the base $\Lambda$CDM model drawn from the posterior of the lensing-only likelihood (left) and the Planck TT+lowP likelihood (right), coloured by the value of the dark matter density $\Omega_m h^2$. For fixed CMB power spectra (i.e. the right-hand plot) the lensing power spectrum shape is nearly fixed, but the amplitude increases as the matter density increases across the acoustic-scale degeneracy (the accompanying reduction in $A_s$ is sub-dominant). With lensing reconstruction data, as $\Omega_m h^2$ varies the lensing spectrum changes shape, with the amplitude around the best-measured $L = 150$, remaining pinned by the accuracy of the measurement there. A combination of the lensing and Planck TT+lowP data measures the matter density significantly better, with the higher values in the right-hand plot being excluded. Note that the colour scales on the plots are different.
which, in terms of $A_\tau$, $\ell_{eq}$, and $h$ is independent of $h$, as expected, given the parameter dependence of $C_L^{\phi\phi}$ discussed above. Recall that the fairly high power-law dependence with $\ell_{eq}$ comes from the rapid fall-off in the matter power spectrum with scale (and from the dependence on $\Omega_m h^2$ of baryon suppression effects). Approximately the same scaling will also affect other measures of small-scale power, for example $\sigma_8$. From Eq. (E.20), for parameter values of interest $\sigma_8$ and $A_\tau$ are related approximately by

$$\sigma_8^2 \Omega_m^{0.6} \propto A_\tau \ell_{eq}^{3.5}. \quad (15)$$

The parameter direction $\sigma_8 \Omega_m^{0.25}$ is therefore close to the direction in which $A_\tau$ (and hence $L^2 C_L^{\phi\phi}$) is constant for fixed $\ell_{eq}$. The combination $A_\tau \ell_{eq}^{3.5}$ is also not far from $A_\tau \ell_{eq}$ of Eq. (14), which remains nearly constant as $\ell_{eq}$ and $A_\tau$ vary within their degeneracy. The $\sigma_8 \Omega_m^{0.4}$ degeneracy direction shown in Fig. 7 and the constraint of Eq. (13) are therefore significantly tighter than the corresponding constraint in the $A_\tau-\Omega_m$ plane, because $\sigma_8$ absorbs some of the degeneracy between matter density and primordial power at a fixed scale.

In terms of $\sigma_8$, a well-determined three-parameter combination is

$$\sigma_8 \Omega_m^{0.25} (\Omega_m h^2)^{0.37} = 1.228 \pm 0.028 \, \text{(lensing only; 68%)}, \quad (16)$$

at 2.3% precision. In terms of power, the 4.6% precision of the square of this parameter combination is still weaker than the template amplitude measurement of Eq. (11a). This is expected, given the approximation of a power-law fit, and that in Eq. (16) we have also marginalized over variations in $n_s$ and $\Omega_b h^2$. Marginalizing out the $\Omega_m h^2$ dependence in Eq. (16), the constraint on $\sigma_8 \Omega_m^{0.25}$ of Eq. (13) is further degraded to 3.5%.

We can also quantify the amplitude of lensing by the rms deflection angle $\langle d^2 \rangle^{1/2}$, which we define via

$$\langle d^2 \rangle \equiv \frac{2000}{L} \sum_{L=2}^{\infty} \frac{(2L+1)}{4\pi} L(L+1) C_{L}^{\phi\phi}. \quad (17)$$

This is approximately an integral over all scales. It is proportional to the primordial fluctuation power $A_\tau$, and scales roughly as a power law in $\ell_{eq}$. A simple argument based on the number of lenses along the line of sight would suggest $\langle d^2 \rangle \propto A_\tau \ell_{eq}^{2}$. This is almost correct, in particular the strong dependence of $C_{L}^{\phi\phi}$ on $\ell_{eq}$ integrates out when forming $\langle d^2 \rangle$ (see Eq. (E.4)). However, there is a further dependence on $\Omega_m$ and $h$ due to the effects of baryon suppression and the late-time decay of the gravitational potential, which is important at low-$L$; we find approximately

$$\langle d^2 \rangle \propto A_\tau \ell_{eq}^{2} (\Omega_m h^2)^{1/5}, \quad (18)$$

by taking derivatives of $C_{L}^{\phi\phi}$ computed with CAMB. The rms is measured at 2.4% precision to be

$$\langle d^2 \rangle^{1/2} = (2.46 \pm 0.06) \, \text{arcmin} \, \text{(lensing only; 68%)}. \quad (19)$$

So far we have only considered a CDM model. However, for most generalizations that are close to CDM, the same scaling also approximately holds, and the constraint direction of $\sigma_8 \Omega_m^{0.25}$ is only weakly model-dependent, although the centroid can shift and also the relation between $\Omega_m$ and $h$. For example, for a model with massless sterile neutrinos parameterized by $N_{\nu}$, the constraint of Eq. (13) is virtually identical, but parameter samples shift towards systematically higher $\Omega_m h^2$ than in CDM to keep the equality scale roughly constant when $N_{\nu} > 3.046$. As a further example, in models with three massive (active) neutrinos with degenerate masses, marginalizing over the mass of massive neutrinos shifts the constraint slightly down, giving

$$\sigma_8 \Omega_m^{0.25} = 0.566 \pm 0.025 \, \text{(ACDM+$\Sigma m_{\nu}$, lensing only; 68%)}. \quad (20)$$

Note that in the neutrino case non-linear corrections from halofit are unreliable away from $\Omega_m \approx 0.3$, which can affect this result at around the 0.01 level.

### 3.5.2. Joint parameter constraints

The small-scale CMB power spectra are only directly sensitive to the primordial power $A_\tau$, after damping by reionization, through the combination $A_\tau e^{-z\tau}$. However lensing also smooths the power spectra at the percent level, which allows the amplitude $A_\tau$ to be constrained via the amplitude of the smoothing effect (and a small transfer of power to small scales), even when $\tau$ is not constrained precisely.\(^9\) The lensing smoothing can be thought of as approximately a convolution of the deflection angle power spectrum with the CMB power spectrum, and hence is mostly sensitive to scales around the peak of the deflection angle power spectrum. We can quantify the amplitude

\(^9\) This direction differs from that in Eq. (14), since the orthogonal direction in the $A_\tau-\ell_{eq}$ plane is not that much worse constrained, so the Fisher information in the three-parameter space is not fully dominated by a single direction.
of the smoothing approximately by the mean-squared deflection angle \( d^2 \) from Eq. (17).

The CMB power spectra determine the angular acoustic scale \( \theta_s \), very accurately, which can be used to eliminate the \( h \)-dependence of \( d^2 \), considered as a function of \( \sigma_8, h, \Omega_m \). Empirically, we find that in the \( \Lambda \)CDM model the CMB power spectrum posterior has \( d^2)^{1/2} \propto \sigma_8 \Omega_m^{0.2} \), close to the \( \sigma_8 \Omega_m^{0.25} \) combination measured more directly by lensing reconstruction\(^{11} \); see Fig. 9. For a flat \( \Lambda \)CDM model the constraint on the latter parameter is

\[
\sigma_8 \Omega_m^{0.25} = 0.621 \pm 0.013 \quad \text{(Planck TT+lowP; 68%). (21)}
\]

The amplitude information here is coming from a combination of the lensing smoothing effect, and information from the CMB power spectrum amplitude combined with the constraint on \( \tau \) from low-\( \ell \) polarization. The lensing-only constraint of Eq. (15) is slightly weaker, but somewhat lower than this (consistent at just over 1\( \sigma \)); see Fig. 7. The combined constraint is tighter and restricted to slightly lower values compared to the Planck power spectrum measurement:

\[
\sigma_8 \Omega_m^{0.25} = 0.609 \pm 0.007 \quad \text{(Planck TT+lowP+lensing; 68%). (22)}
\]

Here, for joint constraints we no longer apply the additional priors used in the lensing-only analysis, and allow for the full linearized CMB power spectrum dependence of the lensing renormalization in the likelihood. The overlap region in the \( \Omega_m-\sigma_8 \) plane also excludes some of the lower Hubble constant values allowed by the power spectrum data, giving a slight shift of the mean in the direction of the higher values preferred by some local measurements (Riess et al. 2011; Humphreys et al. 2013; Efstathiou 2014), as shown in Fig. 9. This could be an additional indication that the lower Hubble constant values from the CMB spectra are at least partly a random statistical fluctuation, in which case joint constraints should be usefully closer to the truth. The joint constraint gives

\[
H_0 = (67.8 \pm 0.9) \text{ km s}^{-1} \text{ Mpc}^{-1} \quad \text{(Planck TT+lowP+lensing; 68%)}, \tag{23}
\]

about 0.5\( \sigma \) higher than Planck TT+lowP alone, and in good agreement with the constraint from Planck TT+lowP+BAO data.

The measurement of the fluctuation amplitude from lensing, combined with the amplitude of the CMB power spectrum on intermediate and small scales, can also be used to constrain the reionization optical depth independently of low-\( \ell \) polarization. The CMB power spectra themselves provide a weak constraint via the lensing smoothing, which is significantly improved by using the additional information in the lensing reconstruction. Figure 10 shows the constraint when Planck CMB temperature power spectrum constraints, without low-\( \ell \) polarization, are combined with the lensing likelihood. We find

\[
\tau = 0.070 \pm 0.024 \quad \text{(Planck TT+lensing; 68%)}, \tag{24}
\]

\(^{11} \) The empirical parameter dependence of \( d^2)^{1/2} \) on \( \Omega_m \) for samples from the CMB power spectrum posterior differs from what one would infer from Eqs. (15) and (18). These equations assume fixed \( n_s \) and \( \Omega_b h^2 \), which is appropriate for our lensing-only constraints with the assumed priors, but for the CMB samples the fractional dispersion in \( n_s \) and \( \Omega_m \) is comparable to that in \( \sigma_8 \), \( h \), and \( \Omega_m \) and so cannot be neglected.

---

**Fig. 10.** Constraints on the reionization (mid-point) redshift \( z_{\text{re}} \) and \( \sigma_8 \) from a combination of Planck CMB power spectra and the lensing reconstruction, excluding low-\( \ell \) polarization information. The grey band denotes the approximate \( z_{\text{re}} < 6.5 \) region excluded by observations of the spectra of high-redshift quasars (Fan et al. 2006). The lensing data significantly shrink the allowed region of parameter space, preferring lower values of the reionization redshift, in good agreement with the measurement from Planck low-\( \ell \) polarization.

---

**3.5.3. Constraints on extensions to the \( \Lambda \)CDM model**

The CMB power spectra only weakly constrain extended models that provide multiple ways to combine late-time parameters to give the same observed angular diameter distance to recombination. The main Planck CMB power spectrum constraints on these parameters are driven largely by the impact of lensing smoothing on the acoustic peaks, which weakly breaks the geometric degeneracy. As discussed in detail in Planck Collaboration XIII (2016), the power spectrum results appear to prefer larger lensing smoothing than in \( \Lambda \)CDM (in this release, slightly above the 2\( \sigma \) level). It is therefore particularly useful to study joint constraints with the lensing likelihood, which constrains the lensing amplitude more directly and more tightly. Since the lensing-reconstruction power spectrum has an amplitude that peaks slightly **lower** than the \( \Lambda \)CDM predictions from the CMB power spectra, the joint constraint eliminates a large region of parameter space with positive curvature allowed by the power spectrum results. For example, Fig. 11 shows the constraints on the curvature parameter \( \Omega_k \) in non-flat models; the high lensing amplitudes, as show in the figure by the rms deflection angle, are ruled out by the lensing reconstruction, and
the joint constraint is consistent with a flat universe ($\Omega_K = 0$). The improvement in error bars is dramatic, with the CMB power spectra giving

$$\Omega_K = -0.052^{+0.03}_{-0.02} \; \text{(Planck TT+lowP; 68%)},$$

and the joint constraint

$$\Omega_K = -0.005^{+0.009}_{-0.007} \; \text{(Planck TT+lowP+lensing; 68%)}. \; \tag{27}$$

This measurement of curvature from the CMB alone has subpercent precision. External data can also break the geometric degeneracy; the joint BAO contours are shown in Fig. 11 and are consistent. Since the BAO results are independent of fluctuation amplitude, the lensing-reconstruction joint constraint adds significant additional information, shrinking the allowed parameter space compared to Planck+BAO alone.

In addition to curvature, CMB results for dark energy models also suffer a geometric degeneracy, and lensing results can similarly provide additional information; for applications to a variety of dark energy models and modified gravity see Planck Collaboration XIV (2016). Lensing can also improve the limits on many other parameters, though in a less dramatic fashion if the CMB power spectra are themselves able to place a good constraint. Full results for many combinations are available online in the grid tables and parameter chains of

$$\Omega_K = 0.000 \pm 0.001.$$

### 3.5.4. Sensitivity to $L$-range

The results in the previous subsections were obtained using our conservative baseline likelihood, with eight bins in the multipole range $40 \leq L \leq 400$. We now briefly discuss how joint constraints from the Planck power spectra and lensing change for different cuts of the lensing data.

Using the first nine bins of the aggressive binning described in Table 1, covering $8 \leq L \leq 425$, results from

$$\sum m_\nu < 0.145 \text{ eV} \; \text{(Planck TT+lowP+lensing+BAO; 68%)},$$

but using the full $L$-range the posterior peaks slightly (though not significantly) away from zero:

$$\sum m_\nu = 0.16^{+0.08}_{-0.11} \text{ eV} \; \text{(Planck TT+lowP+aggressive lensing +BAO; 68%).} \; \tag{29}$$

As discussed in Sect. 4, the multipole range $300 \leq L \leq 900$ may be unreliable, specifically due to the failure of the $TTTT$ curl test. A priority for future analysis should be to develop a trustworthy likelihood over the full multipole range.

### 4. Consistency and null tests

With multiple frequency bands and the combination of both temperature and polarization data, the Planck full-mission data set provides many opportunities to test internally the lens reconstruction. In this section we present consistency and null tests for the MV lensing potential presented in Sect. 3.

For consistency tests, we perform lens reconstruction using different data/analysis choices than those used for our fiducial MV reconstruction, obtaining an alternative measurement of the lensing potential power spectrum $C_L^\phi$, which we then compare to the baseline MV reconstruction. To compare the test and MV reconstructions more quantitatively, we use a $\chi^2$ statistic for the difference between the bandpowers, which is calculated as

$$\chi^2 = \sum_{i=1}^{N} \sum_{j=1}^{N} \left( \frac{C_i^\phi - C_j^\phi}{\sigma_{\text{test}}} \right)^2,$$

with $\Sigma_{\text{test}}$ is a diagonal covariance matrix for the difference obtained from simulations of the two lens reconstructions. We compare this $\chi^2$ to a set of values determined from simulations, to estimate a PTE. We do this for several possible choices of binning: a single bin for either the conservative ($40 \leq L \leq 400$) likelihood range, or the low-$L$ and high-$L$ ranges ($8 \leq L \leq 40$ and $400 < L \leq 2048$, respectively) that are additionally included in the aggressive likelihood; and the individual bins that span the conservative and high-$L$ multipole ranges. The single-bin tests check for broad-band differences between the two reconstructions, while the multiple-bin tests provide a more sensitive check on shape differences or inaccuracies in the error bars for the two reconstructions.

We group the consistency tests as follows, based on the issues which they are designed to probe.

- “Individual estimator crosses” that test for consistency among the five quadratic estimators used to measure $\phi$.
- “Foreground tests” that use single-frequency maps or different component-separation methods to test for possible foreground contamination.

A15 page 12 of 28
Fig. 12. Summary of lensing power spectrum consistency tests. Upper panel: comparison of the lensing power spectra for the baseline MV reconstruction and several alternative estimators with different data/analysis choices discussed in the text. Lower panels: detailed plots of the difference between each alternative reconstruction and the MV power spectrum, in units of the MV error bars ($\sigma$). The ±1$\sigma$ band is indicated in grey. Error bars on individual data points give the standard deviation of the expected difference from the MV reconstruction for each case, estimated using Monte Carlo simulations.

- “Noise tests” that check that our power spectrum estimates are not biased by instrumental noise, using cross-estimators designed to avoid noise biases.
- “Analysis choices” that test our sensitivity to choices such as the unmasked sky fraction and multipole range.
- “Bias-hardened estimators” in which we use lensing estimators that should be less sensitive to certain systematic and instrumental effects.

In Fig. 12 we plot several of the most important consistency tests, as well as their difference from the MV reconstruction. The $\chi^2$ values associated with the full set of consistency tests are presented in Table 2. The tests themselves are described in more detail in Sects. 4.1–4.5.

In addition to consistency tests, we also perform several null tests in which we apply our lens reconstruction and power spectrum estimation procedure to maps that have been differenced.
Table 2: Amplitude fits for a suite of alternative reconstructions of the lensing power spectrum and comparison to the baseline MCMC lensing power spectrum estimate.

The measured overall lensing amplitude Δσ_0 is given for the conservative (40 ≤ L ≤ 40) multipole range, as well as the lower signal-to-noise ratio (SNR) value for the three multipole ranges. The PTE values are estimated to the distribution from simulations. The SNR values for the baseline MCMC reconstruction, rather than the AMMA estimates and estimate errors, as we have quoted the scatter between the two sets of simulations.

Notes. The measured overall lensing amplitude Δσ_0 is given for the conservative (40 ≤ L ≤ 40) multipole range, as well as the lower signal-to-noise ratio (SNR) value for the three multipole ranges. The PTE values are estimated to the distribution from simulations. The SNR values for the baseline MCMC reconstruction, rather than the AMMA estimates and estimate errors, as we have quoted the scatter between the two sets of simulations.

Notes. The measured overall lensing amplitude \( A \) is given for the conservative \( (40 \leq L \leq 400) \) multipole range, as well as lower and higher multipoles. All should be consistent with zero. The PTE values are estimated by comparison of the \( \chi^2 \) values to the distributions from simulations. PTEs are given for the difference of the overall amplitude from zero, as well as for the \( \chi^2 \) of the difference from zero of the binned spectra.

Fig. 13. Power spectrum null tests discussed in Sect. 4.6. Cyl null tests are denoted by \( \psi \). The individual null test power spectra have been scaled by the factors indicated in each panel for visual purposes. The fiducial (gradient-mode) lensing power spectrum is shown as the dashed line in each panel.

4.1. Individual estimator crosses

With the foreground-cleaned temperature and polarization maps from S2ICA, we can form five distinct lensing estimators, and 15 distinct auto- and cross-spectra. We plot all of these spectra individually in Fig. 14. The lensing amplitudes, as well as PTEs for the differences from the MV reconstruction are given in Table 2. There is a wide variation in the sensitivity of the different estimators, although we see high (greater than 5σ significance) detections of lensing in none of the spectra. 13

13 In the 2015 Planck data release, there is some evidence in the polarization power spectra for uncorrected systematic effects associated with temperature-to-polarization leakage (Planck Collaboration XIII 2016; Planck Collaboration XI 2016). Although we find no evidence for inconsistencies in the polarization-based lens reconstructions, the statistical errors are large and may obscure small systematic effects that are subdominant for the current analysis. Leakage from the CMB temperature anisotropies could impact the lensing analysis in several ways. First, the disconnected (Gaussian) part of the CMB 4-point function is modified, and this would affect both our mean-field and NO corrections (see Appendices A.2 and A.3). These corrections are made using a mix of data and simulations, such that even if the simulations do not fully capture the leakage (note they do include leakage due to main-beam mismatch, for example), the additive bias to the lensing power spectrum is only second-order in any unmodelled effects. The second way that leakage can affect the lensing power spectrum is through changes to the lensing response functions in Eq. (A.13), which propagate through to normalization errors. This should be partially captured by a Monte-Carlo correction that we make to the lensing power spectrum. We have not attempted to quantify more carefully any residual effects of temperature-to-polarization leakage, since, ultimately, the polarization data carries relatively little weight in our final MV reconstruction.
As a further test, we combine several of the spectra with the highest S/N that only use estimator crosses (TT × EE, TT × TE, TT × EB, and EE × TE) into a single “crosses” estimator. This combination of cross-spectra has an order-of-magnitude smaller disconnected noise bias correction than the auto-spectrum of the fiducial MV estimator, with $\Delta C_{L}^{\text{MV, Crosses}} \sim 0.4$, compared to $\Delta C_{L}^{\text{MV, MV}} \approx 4.3$ for the baseline MV lensing reconstruction. The results of this test are presented in Fig. 12 and Table 2. With the crosses power spectrum estimates we are able to test that the lensing amplitude is not biased by errors in the disconnected noise bias correction $\Delta C_{L}^{\text{MV, Crosses}}$ at around the 2% level.

We also form a combined power spectrum estimate using only polarization data (the EE and EB estimators). This “Pol. only” estimator gives an amplitude estimate for the conservative multipole range of $A = 0.76 \pm 0.15$, a 5σ detection of lensing at a level consistent with the fiducial MV reconstruction.

### 4.2 Foreground tests

The SMICA CMB map that is used for our baseline MV reconstruction combines multiple frequency bands as a function of angular scale to reject foregrounds and to produce a single high-fidelity estimate of the CMB. We can also compare to a simpler approach based on individual frequency maps, which we clean by subtracting a dust template. Our baseline results in Planck Collaboration XVII (2014) were based on this approach using 143 GHz and 217 GHz data, with the 857 GHz map projected out during the filtering process as a dust template. In this work we repeat this analysis. We use 857 GHz as a dust template in temperature, and no cleaning in polarization. The results of this test are presented in Fig. 12 and Table 2 with the labels “143 GHz” and “217 GHz”, where it can be seen that we obtain lensing bandpowers that are consistent with the MV reconstruction for the conservative multipole range. In the simulations used to characterize these reconstructions, we add coloured Gaussian noise to the 143 GHz and 217 GHz temperature map simulations, designed to mimic the power of unsubtracted extragalactic foregrounds. For this we use the same source model used in Planck Collaboration XVII (2014). We also add Gaussian power to the polarization maps, designed to mimic the power due to Galactic dust contamination that can be seen on large angular scales. The resulting temperature and polarization simulations have power spectra that agree with those of the data at the percent level in power.

We can also test the stability of the lensing reconstruction to the choice of the SMICA component-separation method over other alternatives such as NILC, SEVEM, and Commander. The results of these comparisons are also shown in Table 2; all are very consistent with the SMICA-based reconstruction over the conservative multipole range, although the PTEs for the overall amplitude at high-$L$ ($400 < L \leq 2048$) are low for NILC and Commander. For the SEVEM and Commander analyses, polarization maps were not available at the high resolution used here ($N_{\text{side}} = 2048$), and so we have limited the comparisons to temperature only.

As a test of Galactic contamination, we also repeat our baseline analysis (performed on a fraction $f_{\text{sky}} = 0.7$ of the sky) using a more aggressive ($f_{\text{sky}} = 0.8$) and more conservative ($f_{\text{sky}} = 0.6$) Galactic mask. These masks are constructed by thresholding maps from the Planck high-frequency channels to achieve the desired sky fraction. In Table 2 we see that for both
alternative sky fractions we estimate lensing bandpowers that are consistent with the baseline.

As a final and very powerful test of high-frequency foreground contamination, we also perform a lens reconstruction in which we use the 353 GHz map as one of the four legs in the trispectrum used to estimate $C_{l}^{TT}$. Based on the approximate frequency scaling of dust (Gispert et al. 2000) we expect that any dust foreground bias $\mathbf{b}_{\text{dust}}$ to the lensing power spectrum estimate that we see in this test will scale roughly as

$$b_{\text{dust}}^{353} \approx 7b_{\text{dust}}^{143} \approx 20b_{\text{dust}}^{143},$$

and so this should provide a sensitive test for such contamination in the SMICA map. The 353 GHz map has significantly more power than CMB+noise-only simulations, due primarily to Galactic dust, and temperature fluctuations from the CIB. To obtain reasonable error bars from the 353 GHz simulations used to characterize this reconstruction, as with the other reconstructions we add an isotropic Gaussian sky signal designed to match the simulation power spectrum to a smoothed power spectrum of the data. When filtering the 353 GHz map, we use the same parameters as used for the SMICA map (except for the beam transfer function), to have the same weight given to different angular scales in the quadratic lensing estimators. As with the 143 GHz and 217 GHz analyses, we project out the 857 GHz map as a dust template from the 353 GHz map in temperature, but make no attempt to subtract foreground contamination in polarization. As can be seen in Fig. 12 and Table 2, we obtain good agreement between the “one leg 353 GHz” reconstruction and the MV lensing power spectrum. Lensing power is detected at 20$\pi$ between the “one leg 353 GHz” reconstruction and the MV lensing power spectrum, as shown in Fig. 12 and Table 2, we obtain good agreement between the baseline.

4.4. Analysis choices

We test the stability of our reconstruction to several analysis choices, re-running the baseline analysis implementing the following changes one at a time.

- Use a high-pass filter in temperature and polarization with $\ell_{\text{min}} = 1000$ rather than $\ell_{\text{min}} = 100$, as adopted in the baseline analysis.
- Use a low-pass filter with $\ell_{\text{max}} = 1500$ rather than $\ell_{\text{max}} = 2048$, as used in the baseline analysis.
- Apodize the lensing convergence estimate before power spectrum estimation, following the analysis in Planck Collaboration XVII (2014). This change reduces the size of the Monte Carlo correction, but does not produce a significant change in the lensing bandpower estimates.

The results of these tests are given in Table 2.

4.5. Bias-hardened estimators

Throughout this paper, we have used quadratic estimators optimized to detect the anisotropic covariance between CMB modes that is induced by (fixed) lensing. These estimators are biased by non-lensing sources of such mode coupling, including effects such as galaxy and point-source masking, inhomogeneous instrumental noise, and beam asymmetries. As discussed in Sect. 2, we estimate these biases using Monte Carlo simulations and subtract them as a “mean-field” contribution from the estimated lensing potential (as in Eq. (A.17)). A complementary method, which is less reliant on the quality of the Monte Carlo simulations used to perform this debiasing, is the bias-hardening procedure advocated by Namikawa et al. (2013). In this approach, one constructs a new quadratic lensing estimator that is orthogonalized to worrisome sources of bias. The construction of these estimators is reviewed in Appendix B. In the analysis here we focus on temperature-only bias-hardened estimators to investigate the effects of bias-hardening, because mean-field corrections are much smaller in polarization than in temperature. We denote these estimators as $\hat{\phi}_{TT} - X$, where $X$ denotes the bias(es) that are orthogonalized against. Here, we consider the biases due to masking ($M$), inhomogeneous noise ($N$), and the shot noise due to unresolved point sources ($S$). As discussed in Osborne et al. (2014), the source-hardened estimator $\hat{\phi}_{TT} - S$ also reduces contamination from effects such as the cross-correlation between the unresolved sources and the lensing potential.

Mean-field corrections are largest at low-$L$ (the power spectrum of the mean-field correction is larger than the fiducial lensing potential power spectrum for $L \leq 100$), and so we begin by looking closely at these scales. In Fig. 15 we plot the power spectra of the mean-fields for each of the bias-hardened estimators. In the lower panel we also plot the difference between each estimator and the non-bias-hardened $TT$ estimator. For $L \geq 8$, we see agreement between all of the bias-hardened estimators and the non-bias-hardened reconstruction, regardless
Half-ring difference: the Planck observation strategy consists of scanning the sky in rings with an opening angle of approximately 85°. Each scan ring is observed for between 39 and 65 minutes, and then the satellite is repointed. This leads to a natural “half-ring” null test in which we run our standard lensing estimator on the half-difference of maps constructed from the first and second half of each scanning ring, which should consist entirely of noise. The PTE for the spectrum of the lensing reconstruction estimated from these half-ring difference maps is rather low for the conservative multipole range (see Table 3). Since the maps should be only noise by construction, to obtain an acceptable χ² for the power spectra of reconstructions based on such maps requires very good modeling of the instrument noise. As can be seen from the factor of 200 scaling applied in Fig. 13, the impact on the reconstructed $C_\ell^{\phi\phi}$ of minor errors in the noise modeling that likely drive the low PTEs for the null test should be negligible.

**Fig. 15. Upper:** power spectrum of the low-$L$ mean-field (measured from Monte Carlo simulations) for the $TT$ lensing estimator as well as several bias-hardened estimators. The mean-field power spectrum of the $TE$ lensing estimator is plotted for comparison, and the fiducial lensing potential power spectrum is shown in dashed black. To avoid visual clutter we have not shown the source-hardened estimator $TT = S$; its spectrum is midway between the noise-hardened ($TT - N$) and mask-hardened ($TT - M$) cases. **Lower:** power spectra of the differences between the $TT$ lensing estimate and the bias-hardened reconstructions or the $TE$ reconstruction (with the same colour scheme as in the top panel). The expected power spectra of the differences, estimated from simulations, are plotted as black dotted lines.

of the much smaller mean-field corrections for the former. We have also used the bias-hardened estimators to measure the lensing potential power spectrum on smaller scales. In Fig. 12 and Table 2 we report lensing handpower estimates using the bias-hardened estimators, which we find to be consistent with the baseline MV reconstruction for $L \leq 400$.

### 4.6. Null tests

In addition to the consistency tests described above, we have also performed several direct null tests, either using estimators or maps for which the lensing signal is expected to be zero. These are plotted in Fig. 13, and significance statistics for each are given in Table 3. We discuss them in more detail below.

**Half-mission difference:** noise that is correlated between rings (for example, due to glitches and destriping) can be nulled in the half-ring difference. Another differencing approach, which avoids this problem, is to divide the entire mission into two halves that are then differenced. This half-mission difference requires a slightly larger analysis mask, to account for the fact that the sky coverage is imperfect in both the first and second halves of the mission and some pixels are missed. The PTEs for the half-mission test are reasonable.

**Curl-mode estimators:** in general, deflections due to lensing can be decomposed into gradient ($\phi$) and curl ($\psi$) modes. The curl modes are expected to be consistent with zero for lensing by scalar perturbations at Planck reconstruction noise levels. We construct curl-mode power spectrum estimators, analogous to those used for the gradient lensing modes, and measure their power spectra. Full-sky weight functions for these estimators are presented in Namikawa et al. (2012). Note that although they do not couple directly to the lensing potential, the curl power spectra do receive “N1”-type contributions from the lensing trispectrum, which we estimate analytically and subtract as with the $C_\ell^{\phi\phi}$ power spectrum estimates. We do not make “PS” or “MC” corrections for the curl-mode power spectra. In Table 3 we report estimated amplitudes for a signal with the shape of the fiducial lensing power spectrum $C_\ell^{\phi\phi}$ in the curl estimates. These amplitudes are all consistent with zero at better than 2σ, with the exception of the $TT$ reconstruction over the high-$L$ range (400 $< L \leq 2048$). Indeed, there is mild evidence for a broad feature in the $TT$ curl-mode reconstruction centred around $L = 500$ (see Fig. 13), which drives the low PTE of the $TT$ curl-mode power spectrum over the high-$L$ multipole range. Considering $TT$ alone, the average curl power is low by about 2.9σ in the high-$L$ range, which is suggestive but not clearly unacceptable given the number of tests performed. Combined with the polarization reconstructions, which on their own appear consistent, the MV estimate remains low but only at 2σ over the high-$L$ range. Since the origin of this feature in the curl-mode spectrum is currently not understood, we have chosen to adopt the conservative multipole range for the baseline Planck 2015 lensing likelihood. This multipole range has little overlap with that covered by the curl-mode feature and was determined in advance of the curl result as it retains the majority of the S/N in the reconstruction.

### 5. Conclusions

We have presented a first analysis of gravitational lensing in the Planck 2015 full-mission data set. Using temperature and polarization data, we make the most powerful measurement of
CMB lensing to date, with an overall significance of around $40\sigma$. This paper is accompanied by the public release of the lensing potential map (as well as simulations that can be used to characterize the map, e.g. for cross-correlation analyses with external data) and a conservative lensing bandpower likelihood.

We have performed a number of tests to verify the internal consistency of the lens reconstruction, in particular we have tested the compatibility between individual temperature and polarization estimators, sensitivity to various analysis choices, and possible foreground contamination. Given Planck’s unique full-sky coverage, the full-mission maps are unlikely to be displaced as the most powerful data set for cosmological lensing analysis for the next several years (until high signal-to-noise $E$- and $B$-mode polarization measurements can be made on sufficiently large sky fractions). There is some room, however, for improvement on the analysis presented here. The inverse-variance filtering we have used does not account for variations in the instrument noise level across the sky, which could be incorporated to reduce the reconstruction noise (particularly in polarization, where instrumental noise dominates the signal). We have high-pass filtered all results to $L \geq 8$, due to concerns about the lensing mean-field correction. A more aggressive analysis could potentially remove this cut. The conservative $L \leq 400$ cut that we make in our baseline likelihood, imposed because of mild evidence of a broad feature in curl-mode tests beyond this range, might also be relaxed in a future analysis, although only with minor improvements in the statistical power of the likelihood.

The microwave background is a unique source for lensing studies, as the most distant and well-understood source plane, and the Planck Collaboration acknowledges the support of: ESA; CNES and CNRS/INSU-IN2P3-INP (France); ASI, CNR, and INAF (Italy); NASA and DoE (USA); STFC and UKSA (UK); CSIC, MINECO, JA, and RES (Spain); Tekes, AoF, and CSC (Finland); DLR and MPG (Germany); CSA (Canada); DTU Space (Denmark); SER (Switzerland); RCU (Norway); SFI (Ireland); FCT (Portugal); ERC and PRACE (EU). Appendix A: Pipeline

In this appendix we provide a more detailed technical overview of the pipeline that we use to extract lensing information from the Planck maps. Starting from input CMB sky maps the pipeline has the following three distinct analysis stages.

1. Filtering. In this step, we perform a linear operation on the maps, which performs three tasks.
   a. Mask out regions of the sky that may be contaminated by point sources or residual foreground emission (primarily from the Galaxy).
   b. Deconvolve the instrumental beam and pixel transfer functions.
   c. Downweight noisy modes to allow later steps of the pipeline to produce optimal (in the minimum-variance sense) estimates of the lensing potential and its power spectrum.

Implementation details of the filtering procedure are described in Appendix A.1. The filtering step provides us with filtered CMB temperature and polarization multipoles denoted by $T_{m}^{i}$, $E_{m}^{i}$, and $B_{m}^{i}$.

2. Quadratic Estimators. The filtered CMB multipoles are then fed into quadratic estimators designed to extract the statistical anisotropy that is induced by lensing. These estimators are formed by summing over pairs of CMB fluctuations with a weight function optimized to detect the off-diagonal contributions to their covariance matrix from (fixed) lenses. This step produces maps of the estimated lensing potential $\hat{\phi}$, and is described in detail in Appendix A.2.

3. Power Spectrum Estimation. To estimate the power spectrum of the lensing potential, we exploit the non-Gaussianity induced by lensing. At first order in the power spectrum $C_{\ell}^{\phi\phi}$, lensing generates a contribution to the connected 4-point function (or trispectrum) of the observed CMB, which we probe using auto- and cross-spectra of the 2-point quadratic estimators $\hat{\phi}$ obtained in step (2) of the pipeline. There are two complications here that are worth noting: the auto- and cross-spectra of the lensing estimates have noise biases even in the absence of lensing, which must be carefully estimated and subtracted; and non-Gaussian contamination from unresolved point sources can mimic lensing and bias the reconstructed power spectrum. Our approaches to these issues are described in Appendix A.3.

We now proceed to describe the individual steps of the lensing pipeline in more detail.

A.1. Filtering

At this stage in the pipeline, we have noisy maps of the CMB for both data and simulations. To construct minimum-variance estimates of the lensing potential and its power spectrum, we need to filter these maps to downweight noise-dominated modes, as well as to deconvolve the transfer functions due to the finite beam size and pixelization.

To derive the optimal (minimum-variance) filter to apply, we use a simplified model of the data given by

$$d_i = \sum_j Y_{jk} s_j + n_i,$$

where $d_i$ is a single long vector containing the pixelized $T$, $Q$, and $U$ sky maps. The "pointing matrix" $Y_{jk}$ takes an input sky signal (consisting of $T$, $E$, and $B$ multipoles collectively indexed by $k$), convolves it with a beam and pixel transfer function, and then performs a harmonic transform to map space. The harmonic modes of the sky itself are denoted as $s_k$, and $n_i$ is the map noise realization. We have used indices $i$ and $k$ for quantities in map-space and harmonic-space respectively. Explicitly, the indices $k$ and $i$ are mapped as

$$k \mapsto (X \in \{T, E, B\}, \ell, m) \quad \text{(A.2)}$$

$$i \mapsto (M \in \{T, Q, U\}, p), \quad \text{(A.3)}$$

where $p$ denotes a pixel. In this notation, we model the pointing matrix as

$$\mathbf{Y}_{(M,p),(X,m)} = H_{B}B_{T}R_{X,m}^{M} (\hat{N}_{p}), \quad \text{(A.4)}$$

where $H_{B}$ is the HEALPix (Górski et al. 2005) $N_{\text{side}} = 2048$ pixel transfer function, $B_{T}$ is the effective beam transfer function for the map under consideration, and $R_{X,m}^{M} (\hat{N}_{p})$ represents the real-valued spherical harmonic for field $X$ evaluated at the center of pixel $p$ in map $M$.

If both the sky signal and noise are Gaussian random fields (with covariance matrices $(s_{k}s_{k}') = S_{kk'}$ and $(n_{i}n_{i}') = N_{ii'}$, respectively) then the inverse-variance filtered estimates of the beam-deconvolved signal $\tilde{s}$ are given in matrix notation by (Bunn et al. 1994)

$$\tilde{s} = S^{-1} \left[ Y^T N^{-1} Y \right]^{-1} Y^T N^{-1} d.$$

We use this equation to obtain the inverse-variance filtered $T$, $E$, and $B$ multipoles that are fed into our quadratic estimators, with an additional rescaling discussed below. The large bracketed matrix inverse is performed using conjugate descent with a multi-grid preconditioner, following Smith et al. (2007).

For the purposes of filtering, we use a simplified model for the covariance matrices of $s_k$ and $n_i$ in which they are diagonal in harmonic space and pixel space, respectively, with

$$S = \{s_{(X,m)}(X',m')\} = \delta_{XX'}\delta_{\ell\ell'}\delta_{mm'}C_{\ell}^{XX},$$

$$N = \{n_{(M,p)}(M',p')\} = \delta_{MM'}\delta_{pp'} N_{p}^{M}.$$ $C_{\ell}^{XX}$

Here, $C_{\ell}^{XX}$ is the fiducial theoretical CMB power spectra and $N_{p}^{M}$ gives the noise variance for pixel $p$ in map $M$. With this diagonal assumption, we have ignored the cross-correlation $C_{\ell}^{TE}$ for the purposes of filtering. This is slightly sub-optimal, but has the advantage of allowing the temperature and polarization maps to be filtered independently. It also has the benefit of making analytical calculations for the estimator normalization simpler (see Sect. A.2). Also, for simplicity, we take $N_{p}^{M}$ to be constant over all unmasked pixels and given by

$$N_{p}^{M} = \left( \frac{\pi N_{\text{pix}}^{M}}{10 800} \right)^{2} \frac{N_{\text{pix}}^{M}}{4\pi M_{p}}.$$

Here $N_{\text{pix}}^{M}$ is the map noise level in $\mu$K arcmin, $N_{\text{pix}}$ is the number of pixels in an $N_{\text{side}} = 2048$ HEALPix map, and $M_{p}$ is a mask map (which is zero for masked pixels, and unity otherwise). We always take the noise level to be the same for paired $Q/U$ maps. The mask term in Eq. (A.7) takes the noise level to infinity for masked pixels. In the filtering operation, which only involves the inverse of the noise matrix, this sets masked pixels to zero.
After evaluating Eq. (A.5), we have a set of inverse-variance filtered sky multipoles \( \tilde{s}_{X, \ell m} \) for \( X \in \{ T, E, B \} \). The simplified CMB+white-noise model above results in a slightly sub-optimal filtering procedure since it ignores the following:

1. variations in the noise level across the sky due to the uneven hit distribution (the Ecliptic poles receive more coverage than the equator for the Planck scan strategy);
2. scale-dependence of the noise power; and
3. foreground power.

In Planck Collaboration XVII (2014) we showed that the sub-optimality due to (1) for temperature-based lensing reconstruction was small (accounting for it properly was estimated to improve the uncertainty on the overall lensing amplitude by 4%). The loss will be slightly smaller here for temperature, owing to a more even hit distribution in the full-mission data than in the nominal-mission data used in Planck Collaboration XVII (2014). The loss will be larger for polarization, where noise is a more important part of the total error budget, although we have not evaluated the size of the potential degradation. To compensate for (2) and (3) we make a post-correction by rescaling the modes by a quality factor \( Q^X_\ell \) as a function of scale to obtain final filtered multipoles that are closer to optimal. We denote these as \( \tilde{X}_{\ell m} \), and they are given by

\[
\tilde{X}_{\ell m} = Q^X_\ell \bar{s}_{X, \ell m}.
\]  
(A.8)

These inverse-variance filtered multipoles are the input to the lensing estimators described in Sect. A.2. The choice of \( Q^X_\ell \) is discussed below.

For analytical calculations, it is useful to have an approximation to the filtering procedure that is diagonal in harmonic space (i.e. neglecting the small amount of mode-mixing induced by the masking). In this approximation, the filtered multipoles are given by

\[
\hat{X}_{\ell m} \approx F^X_\ell X_{\ell m} + \tilde{n}_{\ell m},
\]  
(A.9)

where \( \tilde{n} \) is a noise realization and

\[
F^X_\ell = \frac{Q^X_\ell}{C^X_\ell + N^{XX}_\ell}.
\]  
(A.10)

Here, \( C^X_\ell \) are the fiducial CMB auto-spectra used in Eq. (A.6), and the quantity

\[
N^{XX}_\ell = (H_\ell B_\ell)^2 \left( \frac{\pi N^{x}_{\text{sky}}}{10 \, 800} \right)^2
\]  
(A.11)

is the pixel- and beam-deconvolved noise power spectrum for the field \( X \), where \( N^{x}_{\text{sky}} \) is the appropriate map white-noise level in \( \mu K \) arcmin. We choose \( Q^X_\ell \) such that

\[
\frac{f_{\text{sky}}}{2(L+1)} \sum_m |\tilde{s}_{X, \ell m}|^2 \approx F^X_\ell,
\]  
(A.12)

where \( f_{\text{sky}} = \sum_p M_p / N_{\text{map}} \) is the unmasked sky fraction and the approximation sign indicates a smoothing over multipoles.

### A.2. Quadratic estimators

Ensemble averaging over a fixed realization of the CMB lensing potential, the CMB covariance matrix acquires off-diagonal elements given by

\[
\Delta(X_{\ell_1 m_1}, Z_{\ell_2 m_2}) = \sum_{LM} (-1)^M \left( \ell_1 \ell_2 L \right) W_{\ell_1 \ell_2 L}^{XX} \phi_{LM},
\]  
(A.13)

with the fields \( X_{\ell m}, Z_{\ell m} \in \{ T_{\ell m}, E_{\ell m}, B_{\ell m} \} \). The covariance response functions \( W^{XX}_\ell \) for the possible field combinations can be found in Okamoto & Hu (2003). They are linear in the (lensed) CMB power spectra, and are only non-zero if \( \ell_1 + \ell_2 + L \) is even for even-parity combinations, e.g. \( TT \) and \( EE \), and \( \ell_1 + \ell_2 + L \) is odd for the odd-parity combinations \( TB \) and \( EB \). Furthermore, the \( W^{XX}_\ell \) are real for the even-parity combinations and imaginary for the odd-parity. We use the off-diagonal covariance to estimate the lensing potential; after the inverse-variance-filtered sky maps are generated, pairs of fields \( \tilde{X}_{\ell m}, \tilde{Z}_{\ell m} \in \{ T_{\ell m}, E_{\ell m}, B_{\ell m} \} \) are fed into quadratic estimators to estimate the lensing potential. A general quadratic estimator is given as a function of input fields \( \tilde{X} \) and \( \tilde{Z} \) as

\[
\tilde{x}_{LM}[\tilde{X}, \tilde{Z}] = \frac{(-1)^M}{2} \sum_{\ell_1 m_1, \ell_2 m_2} \left( \ell_1 \ell_2 L \right) \sum_m \left( \begin{array}{l} m_1 \ell_2 m_2 \end{array} - M \right) W_{\ell_1 \ell_2 L}^{XX} \tilde{X}_{\ell_1 m_1} \tilde{Z}_{\ell_2 m_2},
\]  
(A.14)

where \( W_{\ell_1 \ell_2 L}^{XX} \) is a set of weight functions that define the estimator \( x \), along with the input inverse-variance filtered multipoles \( \tilde{X}, \tilde{Z} \) for a particular map or pair of maps. The choice of \( \tilde{T}, \tilde{E}, \) or \( \tilde{B} \) for \( \tilde{X} \) and \( \tilde{Z} \) depends on the specific estimator \( x \). In most of what follows we shall drop the \( [\tilde{X}, \tilde{Z}] \) unless it is necessary to avoid ambiguity.

Optimal lensing estimators use a matched filter for the lensing-induced covariance of Eq. (A.13). We denote these as \( W^{XX} \) for the fields \( X \) and \( Z \). The temperature-only optimal estimator, for example, uses \( W^{TT} = W^{TT}_{\text{fid}} \), where the “fid” subscript indicates that the lensing weight function is evaluated for the fiducial cosmological model given at the end of Sect. 2. For the odd-parity combinations, the matched filter is minus the covariance response function, e.g. \( W^{TB} = - W^{TB}_{\text{fid}} \). Neglecting the lensing of any primordial B-mode signal (certainly a valid approximation for scales \( \ell_B > 100 \) with Planck polarization sensitivity), generally there are eight possible lensing estimators based on the possible combinations of \( T, E, \) and \( B \). (This reduces to five estimators for our baseline analysis that uses a foreground-cleaned map of the CMB in temperature and polarization, and for which there is no distinction between \( TE \) and \( ET \), for example.)

The quadratic estimators defined by Eq. (A.14) will receive contributions from non-lensing sources such as masking, beam asymmetry, and inhomogeneity of the instrumental noise. We determine and correct for this bias by averaging the reconstruction \( \hat{x}_{LM} \) over Monte Carlo simulations that include these effects, thereby estimating a “mean-field” \( \hat{x}_{LM}^{MF} \) that we then subtract.

The response of a quadratic estimator to the covariance given in Eq. (A.13) (averaged over CMB realizations with a single mode \( \phi_{LM} \) of the lensing potential held fixed) is, in the diagonal approximation of Eq. (A.9),

\[
\langle x_{LM} \rangle = R^{\phi}_{LM} \phi_{LM},
\]  
(A.15)

where

\[
R^{\phi}_{LM} = \frac{1}{2(2L+1)} \sum_{\ell_1 \ell_2} W_{\ell_1 \ell_2 L}^{XX} X_{\ell_1 m_1} \tilde{Z}_{\ell_2 m_2} F^{XX}_{\ell_1 \ell_2 L}.
\]  
(A.16)
As a baseline, all of the results in this paper are obtained using
the fiducial model at the end of Sect. 2 to calculate the \( W^{\phi\phi} \)
that appear in the estimator response. However, for cosmological
parameter sampling with the lensing likelihood the normalization
is recalculated using the appropriate CMB power spectra as the parameter space is explored. This is discussed further in
Appendix C.

Putting the above together, we form estimates of the lensing
potential as

\[
\phi_{\ell M} = \frac{1}{P_L^{\phi\phi}} \left( \hat{x}_{\ell M} - \phi_{\ell M}^{ME} \right). \tag{A.17}
\]

We can also sum the individual estimators into a combined
minimum-variance estimator (MV) as

\[
\phi_{\ell M}^{MV} = \frac{\sum \phi_{\ell M} P_L^{\phi\phi}}{\sum P_L^{\phi\phi}}, \tag{A.18}
\]

where the sum is taken over the eight lensing estimators \((TT, EE, TE, TB, EB, ET, BT,\) and \(BE)\).

Finally, we note an important implementation detail.
Naively, evaluating an estimator of the form in Eq. (A.14) re-
quires \( O(L_{max}^2) \) operations, which would be very computa-
tionally expensive at Planck resolution. Fortunately, all of the
weight functions used in this paper can be re-written as a sum of
separable terms with the following form

\[
W_{\ell_1,\ell_2} = \sum_{j} (-1)^{\ell_1} \sqrt{\frac{(2\ell_1+1)(2\ell_2+1)(2\ell_2+1)}{4\pi}} \left[ \frac{\ell_1 j}{1} \right] \left[ \frac{\ell_2 j}{2} \right] \left[ \frac{L j}{L} \right] \left[ \frac{\ell_2 j}{L} \right] \left[ \frac{\ell_2 j}{L} \right] \left[ \frac{\ell_2 j}{L} \right] \left[ \frac{\ell_2 j}{L} \right] \left[ \frac{\ell_2 j}{L} \right]. \tag{A.19}
\]

This separability leads to estimators that can be evaluated with
\( O(f_{\text{max}}^2 L_{\text{max}}) \) operations in position space as

\[
\hat{x}_{\ell M} = \frac{1}{2} \int d\hat{\mathbf{n}} \sum_{j} \hat{Y}_{\ell M}(\hat{\mathbf{n}}) u_{\ell j} \left[ \sum_{l_1 m_1} Y_{l_1 m_1}(\hat{\mathbf{n}}) w_{l_1 j} X_{l_1 m_1}^{i} \right] \times \left[ \sum_{l_2 m_2} Y_{l_2 m_2}(\hat{\mathbf{n}}) w_{l_2 j} \hat{X}_{l_2 m_2}^{j} \right]. \tag{A.20}
\]

This separability of the weight functions also allows the re-
sponse functions to be calculated quickly analytically, using the
position-space approach given in Dvorkin & Smith (2009) they
can be evaluated in \( O(f_{\text{max}}^2) \) operations\(^{14}\).

A.3. Power spectrum estimation

Ensemble averaging over realizations of both the CMB lensing
potential and the primary temperature and polarization fluctua-
tions, the CMB becomes non-Gaussian. At first order in the lens-
ing potential power spectrum \( C_{\phi\phi} \) this non-Gaussianity is mani-
fest as a connected 4-point function (Hu 2001)

\[
\langle X_{\ell_1 m_1} Z_{\ell_2 m_2} C_{\ell_3 m_3} D_{\ell_4 m_4} \rangle_c = \sum_{LM} \left[ \begin{array}{ccc} \ell_1 & \ell_2 & 1 \\ m_1 & m_2 & \ell_3 \\ M & m_4 & \ell_4 \end{array} \right] (-1)^{\ell_1+M} W_{\ell_1,\ell_2}^{\phi\phi} W_{\ell_3,\ell_4}^{CD} + \text{2 perms.} \tag{A.21}
\]

As might be expected given the presence of the covariance re-
response functions \( W \) in this expression, estimators to extract \( C_{\phi\phi} \)
from the trispectrum can be written using the quadratic estimators
above as building blocks. We write the cross-spectrum of
two quadratic estimators explicitly as

\[
C_{\phi\phi}^{\Delta L_{\text{xy}}} = C_{\phi\phi}^{L_{\text{xy}}} - \Delta C_{\phi\phi}^{L_{\text{xy}}} \|_{00} - \Delta C_{\phi\phi}^{L_{\text{xy}}} \|_{11} - \Delta C_{\phi\phi}^{L_{\text{xy}}} \|_{MC} - \Delta C_{\phi\phi}^{L_{\text{xy}}} \|_{PS}. \tag{A.22}
\]

There are several correction terms here, which are discussed in
more detail below. We also plot them for the MV reconstruction based
on the Planck 2015 SMICA maps in Fig. A.1.

The \( \Delta C_{\phi\phi}^{L_{\text{xy}}} \|_{00} \) term represents the disconnected contribution
to the 4-point function, which would be non-zero even in the ab-
sence of lensing. We estimate this term by replacing some of the
data fields with those from two sets of independent simulations
(labelled MC1 and MC2), and then average over realizations as

\[
\Delta C_{\phi\phi}^{L_{\text{xy}}} \|_{00} = \left\{ \begin{array}{l} -C_{\phi\phi}^{L_{\text{xy}}} \|_{11} \|_{00} \|_{11} \|_{MC} \|_{MC} \|_{PS} + C_{\phi\phi}^{L_{\text{xy}}} \|_{MC} - D_{\phi\phi}^{L_{\text{xy}}} \|_{MC} \|_{MC} \|_{PS} \tag{A.23} \end{array} \right.
\]

This method for determining the disconnected bias can be de-
erived from the Edgeworth expansion of the lensed CMB (Regan
et al. 2010; neglecting the \( T\theta \) and \( E\phi \) correlations). If the sim-
ulations have a covariance differing from reality by a linear (in

\(^{14}\) A sample implementation of these weights can be found at http://
github.com/dhanson/quicklens in the file quicklens/qest/lens.py
general, anisotropic) correction, this form of the N0 estimator using a mixture of data and simulations is insensitive to the correction at linear order (Namikawa et al. 2013). The largest difference we see between simulations and data is about 5% in power before correction, so the quadratic error should be at most about (0.05)^2 = 0.0025, corresponding to an error of less than 0.4σ for aggressive bins at L ≤ 400 rising to around 1.3σ at L = 2000. Since we also match the data calibration, and add isotropic foreground and noise power to the simulations to match the observed amplitude and shape of the power spectrum of the data, the isotropic part of the error is actually close to zero. A residual error only arises at second order due to our inability to capture any statistical anisotropy in the missing foreground and noise power, and hence should be much smaller than the above estimates. This makes the N0 subtraction rather robust, despite it being substantially larger than the signal on small scales. Furthermore, the mixed form reduces correlations of the lensing power spectrum estimates between different multipoles (Hanson et al. 2011) and with the measured CMB power spectra (Schmittfull et al. 2013).

The $\Delta C_{\ell}|_{N0}$ term corrects for the non-Gaussian secondary contractions (the other permutations in Eq. A.21) due to lensing, as discussed in Kesden et al. (2003). We evaluate it using the flat-sky approximation in 2D Fourier space as

$$\Delta C_{\ell,|N0}|_{L,sp} = \left. \frac{1}{R_{L}^{MC_{N0}}} \int \frac{d^2 \ell_1}{(2\pi)^2} \int \frac{d^2 \ell_2}{(2\pi)^2} \right. \times \left[ C_{\ell_1,\ell_2}^{\phi,\phi} W_{L}^{MC}(-\ell_1, \ell_2) W_{L}^{MC}(-\ell_2, \ell_1) + C_{\ell_1,\ell_2}^{\phi,\phi} W_{L}^{MC}(-\ell_1, \ell_1) W_{L}^{MC}(-\ell_2, \ell_2) \right] \times F_{\ell_1}^{\phi} F_{\ell_2}^{\phi} F_{\ell_1}^{\phi} F_{\ell_2}^{\phi} \times W_{L}^{MC}(-\ell_1, \ell_2) W_{L}^{MC}(-\ell_2, \ell_1),$$

(A.25)

where $\ell_1 + \ell_2 = \ell_2 + \ell_2 = L$. Here the weight functions are flat-sky lensing weight functions; they can be found in Hu & Okamoto (2002).

We characterize any differences between the average lensing power obtained on simulations with the input power. This is determined by

$$\Delta C_{\ell,|N0}|_{MC} = \left. \left( C_{\ell,|N0}^{\phi,\phi}[X_{MC_{1}}, Z_{MC_{1}}, C_{MC_{1}}, D_{MC_{1}}] - C_{\ell,|N0}^{\phi,\phi}[X_{MC_{1}}, Z_{MC_{2}}, C_{MC_{1}}, D_{MC_{1}}] \right) - \Delta C_{\ell,|N0}|_{N0}|_{MC_{1}, MC_{2}} \right|_{MC_{1}, MC_{2}}.$$

(A.26)

The MC correction is included to account for possible issues in the estimation of the normalization, mixing of power between power spectrum bins, and errors in the calculation of the N1 bias. Although in principle several of these effects should be included as multiplicative rather than additive corrections, we find that the MC correction is generally small enough (less than 10% of the fiducial lensing power spectrum) that it does not matter at our experimental sensitivity whether we apply the correction additively or multiplicatively.

Finally, we make a correction $\Delta C_{\ell,|N0}|_{ps}$ for the non-Gaussianity due to the shot-noise of unresolved point sources in temperature. This is given by

$$\Delta C_{\ell,|N0}|_{ps} = S^2 \frac{R_{L}^{MC_{N0}}}{R_{L}^{MC_{N0}}} R_{L}^{MC_{N0}} R_{L}^{MC_{N0}} S^2,$$

(A.27)

where $\bar{S}^2$ is an estimate of the shot-noise amplitude and $S^2$ denotes the weight function (non-zero only for TT) defined by

$$W_{L}^{TT} = \frac{(2\ell_1 + 1)(2\ell_2 + 1)(2L + 1)}{4\pi} \left( \ell_1 \ell_2 L \right) \left( \ell_1 \ell_2 L \right).$$

(A.28)

The $R_{L}^{TT}$ is given by Eq. (A.16) but with $W_{L}^{TT}$ replaced by $W_{L}^{TT}$. Following Osborne et al. (2014), the estimate for the shot-noise trispectrum amplitude is obtained in an analogous way to Eq. (A.23), but using the quadratic estimator formed with the point-source weight function above rather than the lensing weight function. The overall source amplitude is then estimated as

$$\bar{S}^2 = \sum_{L}(2L + 1) \frac{(R_{L}^{TT})^2}{(2L + 1)(2L + 1)}.$$

(A.29)

where the sums are taken over $100 \leq L \leq 2048$. Note that $R_{L}^{TT}$ is given by Eq. (A.16) but with both $W_{L}^{TT}$ and $W_{L}^{TT}$ replaced by $W_{L}^{TT}$.

We use Eq. (A.23) to estimate the lensing potential power spectrum, which we then bin into bandpowers for plotting as well as constructing a lensing likelihood. We use Monte Carlo simulations of the power spectrum estimation to construct error bars for these bandpowers. There is one technical point here, which is that the realization-dependent $\Delta C_{\ell,|N0}|_{ps}$ correction term can be cumbersome to compute. Instead, for the purpose of determining error bars, we use a semi-analytical approximation to this term given by

$$\Delta C_{\ell,|N0}|_{MC_{1}, MC_{2}} = \frac{1}{R_{L}^{MC_{N0}}} \frac{1}{4(2L + 1)} \times \sum_{\ell_1 \ell_2} W_{L}^{MC_{1}} W_{L}^{MC_{2}} C_{\ell_1}^{MC_{1}} C_{\ell_2}^{MC_{2}} + (-1)^{\ell_1} \ell_1^{\ell_2} \ell_2^{\ell_2} W_{L}^{MC_{1}} C_{\ell_1}^{MC_{1}} C_{\ell_2}^{MC_{2}},$$

(A.30)

where the empirical power spectra of the filtered fields are

$$C_{\ell}^{MC_{1}} = \frac{f_{\text{sky}}}{2L + 1} \sum_{m} \tilde{X}_{\ell m} \tilde{Z}_{\ell m}.$$

(A.31)

Appendix B: Bias-hardened estimators

The quadratic lensing estimators of Appendix A.2 can be biased by non-lensing sources of statistical anisotropy such as beam asymmetry, noise inhomogeneity, and masking. In our fiducial analyses, we estimate these mean-field biases using Monte Carlo simulations. However, this approach can be sensitive to the fidelity of the simulations, particularly for the reconstruction on large angular scales where the mean-field biases can be orders of magnitude above the lensing signals of interest. As a cross-check, we also take a more data-dependent approach to correcting these biases. As with lensing, most sources of statistical anisotropy in a map can be associated with a covariance response function $W_{\ell}^{TT}$, and a field $\tilde{f}_{\ell}^{\ell}$ that describes the spatial dependence of the anisotropy. It is possible to construct quadratic estimators for $\tilde{f}_{\ell}^{\ell}$, and then calculate and subtract the resulting lensing bias. This procedure amounts to constructing special “bias-hardened” estimators (Namikawa et al. 2013). Given
Appendix C: Power spectrum likelihood

Here, we provide more detail on the components of our lensing likelihood (given in Eq. (3), and copied below for convenience)

\[-2 \log L_\phi = B_\ell^L(C_{\ell}^{\phi\phi} - C_{\ell}^{\phi\phi,th}) [\Sigma^{-1}]^{\frac{1}{2}} B_\ell^L(C_{\ell}^{\phi\phi} - C_{\ell}^{\phi\phi,th}).\]  

The bandpower binning function \( B_\ell^L \) is given by

\[ B_\ell^L = \frac{C_{\ell}^{\phi\phi}\text{fid}}{\sum_{L_\ell} \left( C_{\ell}^{\phi\phi}\text{fid} \right)^2}, \]  

where \( V_L \) is an approximation to the variance of the power spectrum estimate. For a given cross-spectrum between estimators \( x \) and \( y \) we use

\[ V_L^{-1} = \frac{2L + 1}{2\ell_{sky}} R_L^{x,y} R_L^{x,y}, \]

which produces minimum-variance estimates of the lensing amplitude for each bin in the limit that the sample variance of the lenses is negligible (a reasonable approximation for Planck, which is noise dominated on any individual mode).

The dependence of the likelihood on cosmological parameters enters through the “theory” spectrum \( C_{\ell}^{\phi\phi,th} \). This is the expected value of the estimated spectrum at each point in parameter space. It depends on the cosmological parameters \( \theta \) in several ways:

- directly, through the theory spectrum \( C_{\ell}^{\phi\phi}|_{\theta'} \);
- indirectly (but linearly) on \( C_{\ell}^{\phi\phi}|_{\theta'} \), via the theory-dependence of \( N^{(1)} \) (Eq. (A.25)); and
- indirectly, and non-linearly, on the CMB power spectra \( C_{TT}^L, C_{EE}^L, \) and \( C_{BE}^L \) through the estimator normalization and \( N^{(1)} \) (from the theory-dependent covariance \( W \) of Eq. (A.13)).

We neglect any other theory dependence, for example in the MC correction that is hard to quantify. In detail, for a given set of cosmological parameters \( \theta \), we should calculate

\[ C_{\ell}^{\phi\phi,th} = \left( \frac{R_L^{\phi\phi}}{R_L^{\phi\phi,th}} \right)^{\frac{1}{2}} C_{\ell}^{\phi\phi}|_{\theta'} - \Delta C_{\ell}^{\phi\phi}|_{\text{NL, fid}} + \Delta C_{\ell}^{\phi\phi}|_{\text{NL, th}}, \]

where the \( W \) component of the response functions \( R \) in the numerator, as well as the \( N^{(1)} \) term, are calculated using the CMB power spectra for parameters \( \theta \).

Fully recalculating everything for each point in parameter space is prohibitively slow, but for small deviations from the fiducial model we can use a linearized approximation. The dependence on \( C_{\ell}^{\phi\phi}|_{\theta'} \) is already linear, and expanding the CMB power spectrum dependence to linear order about the fiducial model we can write

\[ C_{\ell}^{\phi\phi,th} = C_{\ell}^{\phi\phi}|_{\theta'} + \frac{\text{dln}(R_L^{\phi\phi})}{\text{d}C_{\ell}^{\phi\phi}} \left( C_{\ell}^{\phi\phi}|_{\theta'} - C_{\ell}^{\phi\phi}|_{\text{fid}} \right) C_{\ell}^{\phi\phi}|_{\text{fid}} \]

\[ + M_{Lx,y}^{(1)\phi\phi} \left( C_{\ell}^{\phi\phi}|_{\theta'} - C_{\ell}^{\phi\phi}|_{\text{fid}} \right) + \frac{\text{dln}(R_L^{\phi\phi})}{\text{d}C_{\ell}^{\phi\phi}} \left( C_{\ell}^{\phi\phi}|_{\theta'} - C_{\ell}^{\phi\phi}|_{\text{fid}} \right), \]

where \( j \) sums over the various CMB power spectra. The matrix \( M_{Lx,y}^{(1)\phi\phi} \) (from Eq. (A.25)) gives the exact linear dependence of \( N^{(1)} \) on the lensing potential for fixed CMB power spectra, and can be pre-computed along with the other derivative matrices for the fiducial model. The binned likelihood of Eq. (C.1) then depends on a binned “theory” power spectrum given in the linear approximation by

\[ B_\ell^L C_{\ell}^{\phi\phi,th} = B_\ell^L C_{\ell}^{\phi\phi}|_{\theta'} + M_{Lx,y}^{(1)\phi\phi} \left( C_{\ell}^{\phi\phi}|_{\theta'} - C_{\ell}^{\phi\phi}|_{\text{fid}} \right), \]

where now \( a \) sums over both the \( C_{\ell}^{\phi\phi} \) and CMB power spectra terms, and \( M_{Lx,y}^{(1)\phi\phi} \) can be pre-computed in the fiducial model.

The Planck lensing likelihood consists of bandpower estimates \( B_\ell^L C_{\ell}^{\phi\phi} \) and the covariance \( \Sigma_{ij} \), a set of binning functions \( B_\ell^L \), a set of linear-correction kernels \( M_{Lx,y}^{(1)\phi\phi} \), and the band values of the linear-correction kernel applied to the fiducial spectrum \( M_{Lx,y}^{(1)\phi\phi} C_{\ell}^{\phi\phi}|_{\text{fid}} \). Note that since the lensing estimator is independent of the CMB calibration, for a theory model \( C_{\ell}^y \) and map calibration parameter \( y_{\text{cal}} \), the theory CMB power spectra that are used in Eq. (C.6) are those matched to the data, i.e. \( C_{\ell}^{\phi\phi}|_{\theta'} = C_{\ell}^{\phi\phi}|_{y_{\text{cal}}} \).

When evaluating “lensing-only” likelihoods, where the CMB power spectra are only very weakly indirectly constrained, we fix the \( C_{\ell}^{\phi\phi}|_{\theta'} \) used in the linear correction to a best-fit to the full data. When calculating joint lensing and CMB results, the correction depends on the CMB power spectra at each point in model space.

Appendix D: CIB model

The cosmic infrared background (CIB) is a diffuse sky signal which begins to dominate over the CMB at frequencies \( \nu \gtrsim 300 \text{ GHz} \). It is generated by dust that is heated by UV light from young stars and then re-radiates thermally in the infrared. The CIB contains approximately half of the total extragalactic stellar flux, and has excellent redshift overlap with the CMB lensing potential (Song et al. 2003). In Sect. 3.2 we use the CIB as a tracer of the lensing potential to estimate the lensing-induced B-mode signal. This requires a model for the cross-correlation between the CIB and the lensing potential. We calculate this in the Limber approximation as (Limber 1954)

\[ C_{\ell}^{\phi CIB} = \int \frac{dk}{k^2} K_{L}^{\phi CIB}(\chi) K_{L}^{\phi}(\chi) P(k = L/\chi, \eta_0 - \chi), \]

where \( P(k; \eta) \) is the (non-linear) matter power spectrum at comoving wavenumber \( k \) and conformal time \( \eta \). The lensing kernel in flat models is given by

\[ K_{L}^{\phi}(\chi) = \frac{3\Omega_m H_0^2}{a(\chi)} \left( \frac{\chi - k}{\chi} \right) \left( \chi - k \right), \]
where $\sigma_8$ is the scale factor at conformal time $\eta_0 - \chi$ and $\chi_s$ denotes the last scattering surface at $z \approx 1100$. To model the CIB, we use the simple SSED model of Hall et al. (2010), which has a kernel given by

$$K_{\text{CIB}}^L(\chi) = b_c \frac{\chi^2}{(1+z)^2} \exp\left(-\frac{(z-z_c)^2}{2\sigma_c^2}\right) f_r(1+z),$$

(D.3)

where $b_c$ is an overall normalization and $z_c = \sigma_c = 2$ describe the redshift distribution of the CIB intensity. The redshift $z$ is evaluated at conformal time $\eta_0 - \chi$. The spectral energy distribution (SED) of a typical CIB source is described by $f_r$. It is modelled as a modified blackbody with temperature $T = 34$ K, and spectral index $\beta = 2$ up to a threshold $\nu' = 4955$ GHz, where it transitions to a power-law decay with index $\alpha = 2$:

$$f_r = \begin{cases} \exp\left(\frac{\nu}{\nu'} - 1\right)^{-1} \nu'^{\beta+3} & (\nu \leq \nu'), \\ \exp\left(\frac{\nu}{\nu'} - 1\right)^{-1} \nu'^{\beta+3} (\nu')^{-\alpha} & (\nu > \nu'). \end{cases}$$

The precise value of $\nu'$ is chosen to match smoothly the slope of $f_r$ on both sides of the transition frequency. In this model, the modified blackbody component of the SED is generally what we observe; even at an observation frequency of 1200 GHz (i.e. 250 $\mu$m), the power-law transition does not occur until $z \approx 4$. Our theory curve is plotted in Fig. D.1, as well as the measured cross-correlation of the Planck 2015 545 GHz map with the MV lensing potential estimate (over 40% of the sky). In addition we have plotted the bandpowers from the rigorous analysis presented in the Planck 2013 data release (Planck Collaboration XVIII 2014). We have set the normalization $b_c$ for the theory curve such that the overall amplitude is consistent with both measurements.

**Appendix E: Parameter dependence of $C_L^{\phi\phi}$ in $\Lambda$CDM models**

In this appendix we discuss the dependence of the lensing potential power spectrum at multipoles $L \gtrsim 100$ on the parameters of $\Lambda$CDM models, providing results that are used in the discussion of the “lensing-only” constraints in Sect. 3.5. Since these constraints adopt a prior on $n_s$ that is rather tighter than the resulting posterior widths for $\Omega_m h^2$ and $h_0$, we ignore dependencies on $n_s$ throughout this appendix. We caution the reader that for joint constraints, or fits to the CMB power spectra alone, fractional variations in $n_s$ can be comparable to those in $\Omega_m h^2$ and $h$, so the dependence of $C_L^{\phi\phi}$ on $n_s$ cannot be ignored. The dependence of $C_L^{\phi\phi}$ on the matter density was recently discussed in Pan et al. (2014); we follow their discussion closely.

For multipoles $L \gtrsim 20$, the angular power spectrum of the lensing potential can be Limber-approximated as

$$L^2 C_L^{\phi\phi} = 4 \int_0^{\nu_L} \left(\frac{\nu}{\nu'}(k^2 P_{\Psi}(k L)/\chi; \eta_0 - \chi)(1 - \chi(\nu'))^2 \right) d\chi,$$

(E.1)

in spatially-flat models. Here, $P_{\Psi}(k; \eta)$ is the equal-time dimensional power spectrum of the Weyl potential $\Psi$. Well after baryon decoupling, we have

$$k^2 P_{\Psi}(k; \eta) \propto k^2 \rho_b(k) T^2(k) g^2(a),$$

(E.2)

where $\rho_b(k)$ is the baryon power spectrum of the primordial curvature perturbation $\mathcal{R}$, $T(k)$ is the transfer function, and $g(a)$ is the growth function for the Weyl potential at scale factor $a$ normalized to unity at high redshift. In $\Lambda$CDM,

$$g(a) = \frac{5 \Omega_m E(a)}{2a} \int_0^{a'} \left(\frac{\nu'}{\nu(a')}\right)^3 \frac{da'}{[a'(E(a'))]^3},$$

(E.3)

where $\Omega_m$ is the matter fraction at the present and $E(a) \equiv H(a)/H_0$. For $\Omega_m \approx 0.3$, the current value of the growth function is $0.78$, and $\ln g/d\ln \Omega_m = 0.23$. Close to $\Omega_m = 0.3$, we can approximate the cosmology dependence of the growth function at redshift zero as $g(a = 1) \approx 0.78(\Omega_m/0.3)^{1/2}$. For $L > 100$, the lensing potential mostly probes early enough times that $g(a = 1)$ is a good approximation (Pan et al. 2014). However, if we wish to express the amplitude of $P_{\Psi}(k)$ at early times in terms of $\sigma_8$ (at the present), we require $g(a = 1) = 1$.

The transfer function is normalized to unity for $k \ll k_{eq}$, where $k_{eq} \approx 10^{-2} \text{Mpc}^{-1}$ the inverse of the comoving Hubble parameter at matter-radiation equality. For $k \gg k_{eq}$ we have $T(k) \approx (k/k_{eq})^{-2} \ln(k/k_{eq})$. Keeping the radiation energy density fixed today, $k_{eq} \propto \omega_m$, where $\omega_m \equiv \Omega_m h^2$. As well as $k_{eq}$, the other scales that enter the transfer function are the sound horizon at the drag epoch (where baryons dynamically decouple) $r_{\text{drag}}$, and the diffusion scale $k_D$. The broad-band shape is controlled by $k_{eq}$, while $r_{\text{drag}}$ determines the scale below which baryon suppression effects are important (see e.g. Eisenstein & Hu 1998). The non-zero baryon fraction $\omega_b/\omega_m$ tends to suppress the transfer function on small scales since (essentially) unclustered baryons impede the growth of the CDM density perturbation up to the time after decoupling when baryon infall into the CDM potential wells is complete. The further effect of baryons is to imprint baryon acoustic oscillations in the transfer function for $k_{\text{drag}} > \pi$ and $k \leq k_{eq}$. Baryon acoustic oscillations have little impact on $C_L^{\phi\phi}$ since they are washed out by the line-of-sight integration. We therefore ignore them here and, where an explicit form for the transfer function is required, for illustrative purposes we use the “no-wiggle” fit of Eisenstein & Hu (1998). For the range of parameters of interest, we can assume that the

---

15 We ignore the small effects of non-zero neutrino mass in the base $\Lambda$CDM model, so that the linear growth of structure is scale-independent well after baryon decoupling.
physical baryon density $\omega_b$ is fixed, so the transfer function can be thought of as a function of $k/k_{eq}$, $k_r\ell_{drag}$ and $\omega_m$.

Ignoring departures of the growth function from unity and approximating $P_{\ell^*}(k)$ as scale-invariant with amplitude $A_s$, we can write

$$L^4C^\ell_\ell \propto A_s\ell_{eq}\int_0^1 dx \left(\frac{L}{\ell_{eq}x}\right)^2 \left(\frac{L}{\chi_\ell x}\right)^2 (1-x)^2, \tag{E.4}$$

where $x = \chi/\chi_\ell$ and $\ell_{eq} \equiv k_{eq} \chi_{eq} \approx 140$. The $A_s\ell_{eq}$ prefactor has a simple physical interpretation: CMB photons are typically deflected by $\ell_{eq}$ lenses of size $k_{eq}^{-1}$, and each mean-squared deflection is proportional to $A_s$, giving a mean-squared deflection proportional to $A_s\ell_{eq}$. Given the $k$-dependencies of the transfer function through $k/k_{eq}$ and $k_r\ell_{drag}$, and its direct parameter-dependence on $\omega_m$, we see that in $\Lambda$CDM, the lensing power spectrum at $L \geq 100$ is most strongly determined by only $A_s, L/\ell_{eq}, L/\ell_{drag}$, and $\omega_m$. Here, the multipole $\ell_{drag} \equiv \chi_{\ell}/r_{drag}$ characterizes the BAO scale at last-scattering. The integral in Eq. (E.4) determines the shape of the lensing power spectrum. Defining

$$f(L, \ell_{eq}, L/\ell_{drag}, \omega_m) \equiv \int_0^1 dx \left(\frac{L}{\ell_{eq}x}\right)^2 \left(\frac{L}{\chi_\ell x}\right)^2 (1-x)^2, \tag{E.5}$$

the dependence on the cosmological parameters (e.g. $\ell_{eq}$) in the vicinity of the fiducial model is, at $L$, approximately a product of power laws with exponents

$$n^eq_{\ell_{eq}} \equiv -\partial \ln f_L/\partial \ln(L/\ell_{eq})|_{lid}, \tag{E.6}$$

$$n^drag_{\ell_{eq}} \equiv -\partial \ln f_L/\partial \ln(L/\ell_{drag})|_{lid}, \tag{E.7}$$

$$n^n_{\ell_{eq}} \equiv \partial \ln f_L/\partial \ln \omega_m|_{lid}, \tag{E.8}$$

each evaluated for the fiducial cosmology. Note also that $n^eq_{\ell_{eq}}$ and $n^drag_{\ell_{eq}}$ determine the local power-law slope of $C^\ell_\ell$, with

$$n^eq_{\ell_{eq}} + n^drag_{\ell_{eq}} = -d\ln(L^4C^\ell_\ell)/d\ln L. \tag{E.9}$$

On the angular scales where Eq. (E.4) is valid, only modes with $k > k_{eq}$ contribute. For these scales, $(k/k_{eq})^2$ $(k)$ increases with $k_{eq}$ giving $n^2_{\ell_{eq}} > 0$ (and monotonic increase of $n^eq_{\ell_{eq}}$ with $L$). Around $L \approx 200$, the scales that dominate the $S$ of an lensing amplitude measurement from Planck, $n^0_{\ell_{eq}} \approx 0.9$. This, and $\Lambda_s$, dominate the parameter dependence of $C^\ell_\ell$. The effect of baryon suppression is reduced as $\omega_m$ increases at fixed $\omega_b$, and the suppression scales with $L$. Around $L \approx 200$, we find $n^0_{\ell_{eq}} \approx 0.3$, which gives a small, but non-negligible, further parameter dependence to $C^\ell_\ell$. Finally, the dependence on $\ell_{drag}$ is very small, since $n^drag_{\ell_{eq}} \lesssim 0.15$ (with peak value around $L \approx 100$, roughly equal to $\ell_{drag}$). Putting these pieces together, we find a dependence of $L^4C^\ell_\ell$ on cosmological parameters scaling approximately as

$$L^4C^\ell_\ell \propto A^s_{\ell_{eq}}k_{eq}^{n^eq_{\ell_{eq}}}L^{n^drag_{\ell_{eq}}}/\omega_m^{n^n_{\ell_{eq}}}, \tag{E.10}$$

for $L \geq 100$, where the dependence on $\ell_{drag}$ is very weak.

We can express the parameter dependence of $C^\ell_\ell$ in terms of the usual $\Lambda$CDM parameters. The comoving distance to last-scattering, $\chi_\ell$, is

$$\chi_\ell \equiv \int_0^{1} \frac{dt}{aH(t)}. \tag{E.11}$$

where $a_*$ is the scale factor at last-scattering (whose dependence on cosmology can be ignored here). At fixed radiation energy density today, the dependence on $\Omega_m$ and $h$ is approximately

$$\chi_\ell \propto \Omega_m^{-0.4}h^{-1}. \tag{E.12}$$

around $\Omega_m = 0.3$ and $h = 0.7$.\footnote{We ignore the small dynamical effects of $\sigma_8$ calculations with CAMB.} This differs from the $(\Omega_m h^2)^{-1/2}$ of an Einstein-de Sitter universe due to the late-time effects of $\Lambda$. Using $k_{eq} \approx \Omega_m h$, we have

$$\ell_{eq} \propto \Omega_m^{-0.15}h^{-0.5}. \tag{E.13}$$

At fixed baryon density, the sound horizon at the drag epoch scales like $r_{drag} \propto \omega_m^{-0.25}$ in the vicinity of the fiducial model, so that

$$\ell_{drag} \propto \Omega_m^{0.15}h^{-0.5}. \tag{E.14}$$

Using these dependencies in Eq. (E.10), we find

$$L^4C^\ell_\ell \propto A_s (\Omega_m^{0.6}\Omega_m^{0.15}h^{-0.2}k_{eq}^{-4}). \tag{E.15}$$

where $n_L \equiv n^eq_{\ell_{eq}} - 0.5 \times n^drag_{\ell_{eq}} + 2n^n_{\ell_{eq}}$ is approximately 1.5 at $L \approx 200$. The remaining dependence on $\Omega_m$ is very weak, with $0.15 \times n^drag_{\ell_{eq}} - 0.2 \times n^n_{\ell_{eq}} \approx -0.05$ at $L \approx 200$. Equation (E.15) gives the main dependence of the lensing power spectrum on the cosmological parameters of $\Lambda$CDM models at multipoles $L \geq 100$.

### E.1. Normalization by $\sigma_8$

The dependence of the lensing power spectrum on $A_s$ can be eliminated in favour of $\sigma_8$. We use the Poisson equation to relate the dimensional matter power spectrum at $a = 1$ to that of the Weyl potential, giving

$$P_{\sigma}(k; a) = \omega_m^{-2}k^4P_{\phi}(k; a = 1). \tag{E.16}$$

It follows that the variance of the density contrast in spheres of radius $R$ is

$$\sigma_R^2 \propto \omega_m^{-2}g^2(a = 1) \int_0^\infty dk k^3P_{\phi}(k)T^2(k)W^2(kR) \propto A_s k^4\omega_m^{-2}g^2(a = 1) \int_0^\infty dx x^3P(x)W^2(x(kR)), \tag{E.17}$$

where we have assumed that $P_{\phi}(k)$ is scale-invariant in passing to the second line. The window function

$$W(kR) \equiv \frac{3}{2\pi} \frac{J_1(kR)}{kR} = \frac{1}{(kR)^3}(kR \cos kR - \sin kR), \tag{E.18}$$

is the Fourier transform of a normalized spherical top-hat function of radius $R$; following convention, we take $R = 8h^{-1}$ Mpc.

The integral in Eq. (E.18) is a function of $k_{eq}R$, $k_{eq}r_{drag}$, and $\omega_m$ at fixed baryon density (with the latter two from the transfer function). Evaluating the logarithmic derivative with respect to these parameters at the fiducial values, using the “no-wiggle” transfer function from Eisenstein & Hu (1998), we find that the integral scales as $(k_{eq}R)^{-4}\omega_m^{0.45}$, with only a very weak further dependence on $k_{eq}r_{drag}$, in the vicinity of the fiducial model.

Finally, the parameter dependence of $\sigma_R^2$ is

$$\sigma_R^2 \propto A_s k_{eq}^4\omega_m^{-2}g^2(a = 1)(k_{eq}h^{-1})^{-4}\omega_m^{0.45} \propto A_s \Omega_m^{1.5}h^{-3.5}. \tag{E.20}$$

This parameter dependence agrees well with direct finite-differencing of $\sigma_R^2$ calculations with CAMB.
