Summary

Marine methylotrophs play a key role in the global carbon cycle by metabolizing reduced one-carbon compounds that are found in high concentrations in marine environments. Genome, physiology and diversity studies have been greatly facilitated by the numerous model organisms brought into culture. However, the availability of marine representatives remains poor. Here, we report the isolation of four novel species from North Sea sediment enrichments closely related to the Alphaproteobacterium *Methyloceanibacter caenitepidi*. Each of the newly isolated *Methyloceanibacter* species exhibited a clear genome sequence divergence which was reflected in physiological differences. Notably one strain R-67174 was capable of oxidizing methane as sole source of carbon and energy using solely a soluble methane monooxygenase and represents the first marine Alphaproteobacterial methanotroph brought into culture. Differences in maximum cell density of >1.5 orders of magnitude were observed. Furthermore, three strains were capable of producing nitrous oxide from nitrate. Together, these findings highlight the metabolic and physiologic variability within closely related *Methyloceanibacter* species and provide a new understanding of the physiological basis of marine methylotrophy.

Introduction

Methylotrophs are key players in global marine carbon cycling (Redmond *et al.*, 2010; Chistoserdova, 2011; Halsey *et al.*, 2012; Beck *et al.*, 2013). They are capable of growth on methanol as well as other reduced methylated one-carbon (C1) compounds such as methane, methylamine or formate (Hanson and Hanson, 1996; Trotsenko and Murrell, 2008; Chistoserdova, 2011). Methanol is one of the major oxygenated volatile organic compounds in marine systems with major sources being atmospheric deposition, phytoplankton excretion and the turnover of the potent greenhouse gas methane emitted from the seafloor and organic rich sediments by methane-oxidizing methylotrophs (further denoted as methanotrophs or MOB). Ocean surface concentrations of methanol can reach up to 100 nM in the Pacific Ocean (Singh, 2003) and 300 nM in the Northern hemisphere (Galbally and Kistina, 2002), but it is unclear whether oceans are a methanol sink or source to the atmosphere (Williams, 1969; Singh, 2003; Heikes *et al.*, 2002; Carpenter *et al.*, 2004; Sinha *et al.*, 2007). Methylotrophic bacteria, together with mixotrophic eukaryotes, represent an oceanic sink for methanol, mainly through its use as energy source and to a lesser extent as carbon source (Dixon *et al.*, 2011). Using DNA-stable isotope probing *Methylophaga* spp. and other, novel *Gammaproteobacteria* were found as major consumers of methanol and methylamine, in surface seawater (Neufeld *et al.*, 2007). Cultivation-based studies have demonstrated that Alphaproteobacterial SAR 11, which are some of the most abundant heterotrophs in the oceans, use one-carbon compounds like methanol for energy generation (Sun *et al.*, 2011), while the Betaproteobacterial OM43 clade is a dominant marine methylotroph (Giovannoni...
et al., 2008; Sowell et al., 2011) in productive coastal waters, including in the North Sea (Sekar et al., 2004).

Despite their crucial role in marine carbon cycling, only a handful of marine methanol oxidizers and even fewer methane oxidizers, the latter all belonging to the Gammaproteobacteria, have been isolated and physiologically characterized (Sieburth et al., 1987; Lidstrom, 1988; Fuse et al., 1998; Giovannoni et al., 2008; Boden et al., 2011; Huggett et al., 2012; Hirayama et al., 2013; Hirayama et al., 2014; Takeuchi et al., 2014a,b; Tavormina et al., 2015; Jimenez-Infante et al., 2016). Most methanotrophic surveys focused on high methane-loaded systems like mud volcanoes (Niemann et al., 2006), vent fields (Nercessian et al., 2005) and methane gas seeps (Inagaki et al., 2004; Yan et al., 2006; Hävelsrud et al., 2011). These areas reveal a dominance of Gammaproteobacterial methanotrophs affiliated to the Methylococcaceae as the most abundant aerobic methanotrophs, with occasional molecular detection reports of Alphaproteobacterial methanotrophs (Inagaki et al., 2004; McDonald et al., 2005; Nercessian et al., 2005; Niemann et al., 2006; Valentine, 2011). Interestingly, pmoA amplicon sequencing demonstrated that more than 80% of detected sequences were attributed to novel species of as yet uncultured methanotrophs (Yan et al., 2006; Hävelsrud et al., 2011; Abdallah et al., 2014). As such, novel cultures remain pivotal to unravel complex biological traits important to marine biogeochemistry, especially since reports on high metabolic versatility among congenerics and even conspecifics (i.e. belonging to the same genus and species respectively) is accumulating (Vorobev et al., 2013; Beck et al., 2014; Hoefman et al., 2014). This metabolic versatility is a major confounding factor for linking biodiversity to ecosystem functions and further warrants the capture of a greater representation of marine methylotrophic diversity into pure culture (Hoefman et al., 2014). These cultures should serve to expand understanding of the traits that influence their activity patterns in marine systems such as the capacity to use alternative carbon and energy sources or the interaction with nitrogen and sulfur cycling (Klotz and Stein, 2008; Stein et al., 2011).

We now highlight the metabolic versatility with respect to methylotrophy and nitrogen metabolism among marine methylotrophs, discovered via shotgun sequencing of highly enriched methane-oxidizing cultures and subsequent isolation of the methanotrophs from these enrichments. Within the recently described methylotrophic genus Methyloceanibacter, we found representatives of four novel species. One of these new species is capable of methane oxidation, for which it uses solely the soluble methane monoxygenase (sMMO), making this the first Alphaproteobacterial methanotroph isolated from a marine system, the third methanotrophic taxon only possessing sMMO and the first methanotroph within a non-methanotrophic genus. Furthermore, converging with the species boundaries, Methyloceanibacter spp. displayed a wide physiological variation related to growth kinetics on methanol, and preferences for nitrogen, pH, temperature and salt.

**Results**

**Enrichment and isolation of four novel Methyloceanibacter species**

North Sea sediments from two sampling sites (W04, Vlakte van de Raan; W09, Hinderbanken) were incubated at 20°C with a headspace composition of 20:80 v/v methane/air under conditions mimicking the in situ nutrient availability. Methane oxidation was observed within one to two weeks, and after periodical headspace refreshments during two months, dense cultures were formed. Through extinction culturing under methane atmosphere, transfer of highest positive dilutions and numerous subcultivations over a period of three years, these two methane-oxidizing cultures were highly enriched. Subsequent metagenome sequencing revealed the presence of one highly enriched bacterium in sample W04 (representing 83.10% of the total reads) and two in sample W09 (together representing 87.04% of total reads). All three genomic bins were closely related with the recently described methylotrophic Alphaproteobacterium Methyloceanibacter caenitepidi Gela4T, obtained from marine sediment collected near a hydrothermal vent in Japan (Takeuchi et al., 2014a). Surprisingly, no pmoA genes encoding the particulate methane monoxygenase (pMMO) were detected in the metagenomes. However, one genomic bin in each metagenome contained a complete operon encoding a sMMO, making it very likely that these Methyloceanibacter spp. were responsible for the observed methane oxidation of the enrichment cultures. Furthermore, the second bin in sample W09 seemed to be originating from a methylotrophic Methyloceanibacter sp. without sMMO encoding genes.

In a final effort to obtain pure cultures of Methyloceanibacter, methanol was used as carbon source and small white colonies were obtained on plate after two months. Forty-one Methyloceanibacter isolates (as verified by partial 16S rRNA gene sequencing) were picked up, genotyped with (GTG)5 and Box rep-PCR fingerprinting and grouped into four separate clusters, all distinct from M. caenitepidi Gela4T. One representative was chosen per cluster and designated with strain numbers R-67174, R-67175, R-67176, and R-67177 (Supporting Information Fig. S1). R-67174 was solely isolated from site W04, R-67175 and R-67177 solely from site W09, and R-67176 from both sites. Genomes of all four strains were sequenced (Supporting Information Table S1) and geno-
within the genus Methyloceanibacter (Supporting Information Fig. S2). The strains clearly differed in growth morphology in liquid medium, with R-67174 forming small irregular flocs, R-67175 dense single cell cultures, R-67176 slightly dense single cell cultures with occasionally small flocs and R-67177 attaching firmly to the side of the vials. M. caenitepidi Gela4T also formed single cell cultures, similar to R-67175. All strains formed identical colonies (round, white and convex) on solid media and displayed similar rod-like shaped cell morphology, similar to M. caenitepidi Gela4T, with Gram-negative staining (Takeuchi et al., 2014a).

R-67174 showed a 100% 16S rRNA gene sequence similarity with both methanotrophic genomic bins of the W04 and W09 enrichments, although all isolates representing strain R-67174 originated from WE04. Its methane oxidation capacity was indeed confirmed physiologically and its genome contained a complete operon encoding a sMMO (see below).

C1 metabolism

Use of methane and methanol as sole source of carbon and energy was tested for all Methyloceanibacter strains including M. caenitepidi Gela4T. Only R-67174 demonstrated growth coupled to methane and oxygen decrease and carbon dioxide increase over time (Fig. 1A). The addition of extra carbon dioxide to the headspace had a growth-promoting effect by decreasing the lag phase, as could be seen from the methane oxidation profile (Fig. 1b). This effect was not linked to an acidification of the media as no significant pH shift was measured under increased carbon dioxide concentrations (data not shown). Furthermore cultures grown to stationary phase reached similar maximal cell densities (appr. 23 \( \times 10^7 \) cells/mL) refuting autotrophic growth, which is supported by the lack of Rubisco genes necessary for fixation of the inorganic carbon dioxide into organic carbon. Thus, as R-67174 is an Alphaproteobacterial methanotroph, the effect of carbon dioxide is most likely linked to use of the serine pathway for carbon assimilation (Supporting Information Table S3), which requires one carbon dioxide for each formaldehyde (Chistoserdova, 2011). As was expected from the metagenome data, the genome of R-67174 lacked pmO genes and contained a complete mmoXYBZDC operon for a sMMO (Fig. 1c). MmoX was most affiliated with that of Methylocella silvestris (Dunfield et al., 2003) and Methyloferulla stellate (Vorobev et al., 2011) (92.6 and 91.3% aa similarity) (Fig. 2), both Alphaproteobacterial methanotrophs with solely a sMMO. The genome environments of...
Materials and Methods for details) and are displayed as different upper- and lowercase letters, respectively (combined letters are used to indicate non-significance for multiple variables).

Standard deviations are given between brackets (based on at least three replicate measurements). Significance \( p < 0.01 \) of between-strain differences for growth on methanol and within-strain differences per growth condition for R-67174 were determined via one-way ANOVA (see Materials and Methods for details) and are displayed as different upper- and lowercase letters, respectively (combined letters are used to indicate non-significance for multiple variables).
67177 two xoxF1 copies (and two truncated genes located separately) as well as one complete xoxF3. All XoxF1 grouped into three cluster (Supporting Information Fig. S5; clusters C1, C2, C3), with >90% aa similarities within each cluster. R-67174, R-67175 and R-67177 also have the genomic potential to encode a PQQ-ADH type 9 quinoproteins (Fig. S5) (Keltjens et al., 2014). Unfortunately, there is no clear link between the xoxF gene inventories and the kinetic parameters on methanol. But xoxF expression in methylotrophs containing calcium-dependent MxaF has already been shown in the marine environment for Methylphaga (Grob et al., 2015). So, considering that lanthanides (specifically cerium, lanthanum, praseodymium and neodymium) were detected in the 0.1 to 10 nanomolar range in pore water of the sediment at each sampling site in this study and excess of these lanthanides (specifically cerium, lanthanum, praseodymium and neodymium) were always added to the growth medium (throughout the enrichment procedure and during growth experiments), it is plausible that their differential expression might have contributed to the observed significant strain-dependent differences in growth on methanol.

Differential nitrogen preferences, alternative carbon source utilization and responses to environmental stimuli

Detailed physiological and genomic data revealed clear differences in the nitrogen metabolism between the Methyloceanibacter strains. All strains have the genomic potential to transport and assimilate ammonium via glutamine synthetase – glutamate synthase (GS-GOGAT) (Supporting Information Table S3). While the GS-GOGAT would operate under low ammonium and nitrate concentrations, glutamate dehydrogenase, present in R-67177, and to a lesser extent alanine dehydrogenase, present in R-67175, could be used when ammonium concentrations are high (Supporting Information Table S3) (Lees et al., 1991). Further the presence of other enzymes capable of direct ammonium assimilation, i.e. NAD synthetase, carbamoyl phosphate synthetase and asparagine synthetase, in all strains might further support the assimilation of ammonium (van Heeswijk et al., 2013). Next strains Gela4T, R-67175 and R-67177 encoded enzymes for the transport and assimilatory reduction of nitrate (Supporting Information Table S3). All strains indeed utilized ammonium as sole nitrogen source within a range of 0.5 to 10 mM (Fig. 4; Supporting Information Table S4), with mostly broad concentration range between 2 and 10 mM but with a well-defined preference at 10 mM for R-67176. For nitrate as sole nitrogen source, R-67175 and R-67177 showed highest cell density at 5 mM and Gela4T at 10 mM (Fig. 4; Supporting Information Table S4). Genes for the dissimilatory membrane-bound cytoplasmic nitrate reductase NarG and one or two NarK-type nitrate/nitrite antiporters were found in all genomes except that of the methanotroph R-67174 (Supporting Information Table S3). NarG aa similarity ranged between 82.8-99.8% and its phylogeny agreed with that of the 16S rRNA gene (Fig. 2) and MxaF (Supporting Information Fig. S5), suggesting that R-67174 might have lost the nar operon quite recently as it still contained a narK. Although dissimilatory nitrate reduction was not experimentally verified, nitrous oxide production by Gela4T, R-67175 and R-67177 grown on nitrate was observed at end exponential/early stationary phase (at oxygen concentration between 100-300 μM), suggesting that dissimilatory nitrate reduction proceeds once oxygen is depleted. The amount of produced nitrous oxide appeared correlated with the initial nitrate concentration and 4 to 8% of initial nitrate was converted to nitrous oxide (data not shown). This low conversion rate combined with the absence of denitrification genes in the genomes, the presence of several genes for nitrosative stress response regulators (NsrR, NnrR, NnrS and NnrU) and nitrous oxide production being restricted to strains able to assimilate nitrate led us to hypothesize that nitrous oxide is produced via a nitrite detoxification pathway. Similar to nitrate-reducing Enterobacteriaceae (Smith, 1983; Corker and Poole, 2003; Gilberthorpe and Poole, 2008), high - potentially toxic - levels of produced nitrite could be converted to nitric oxide via the dual action of Nar and/or NirB. However, genes encoding the usual suspects for the further reduction to nitrous oxide, namely dedicated nitric oxide reductases like qNorB and CuωNor or flavohemoglobin Hmp were absent from the genomes. Lastly, the genomes of R-67174 and R-67176 also contained a complete gene inventory for nitrogen fixation (Supporting Information Table S3), with gene organization similar to that of Methylcocella silvestris BL2 and a NifH aa sequence similarity of
Although it was not experimentally verified under low oxygen tension, nitrogen fixation could compensate for the inability to assimilate nitrate under ammonium limitation or provide a competitive benefit in absence of (in)organic nitrogen sources.

Significant strain dependency of growth kinetics on methanol were already described above (Table 1), but, similar to the observed nitrogen preferences, differences became apparent for the different strains in relation to methanol concentrations, alternative carbon source utilization and responses to environmental stimuli (Fig. 4; Supporting Information Table S4). All strains except R-67175 grew with 0.1 to 5% methanol. R-67174 displayed a similar growth over this concentration range, while the others clearly preferred 1–2%. They were also all facultative methylotrophs able to use dimethylcarbonate and formate. In addition, only R-67175 could not utilize acetate, while only R-67174 was unable to grow on ethanol. However, maximal cell densities on these alternative carbon and energy sources were low compared to methanol, except for Gela4T on ethanol and R-67176 on acetate. Both compounds are realistic alternative carbon sources in situ reaching up to 2–33 nM for ethanol (Beale et al., 2010) and from 1 to 10 μM for acetate (King, 1991; Wellsbury, 1995; Wu et al., 1997) in marine sediments. R-67177 seemed to have adapted to a lifestyle of a generalist, without a clear preference for either carbon source. Next to carbon metabolism, variation in growth ranges for salinity, temperature and pH further underlined strain-dependent physiologies of the Methyloceanibacter strains (Fig. 4, Supporting Information Table S4). R-67177 and Gela4T demonstrated the broadest salinity range supporting growth, with no differences in maximum cell density for the former while the latter had an unexpected optimum at 0% salinity (given in situ salinity of 33-35 psu). In contrast, R-67174 and R-67176 needed salt to grow, and R-67175 was limited to a salinity of 3%. Also the temperature range of R-67175 (18–28°C) was narrower than that of the others (18–37°C). Again it was strain-dependent whether maximal cell densities varied with temperature. A similar observation was made for pH, with R-67175 being restricted to pH 6.3 to 7.8.

Discussion

In this study we were able to isolate a set of four marine methylotrophic Methyloceanibacter strains, in addition to the earlier described M. caenitepidi, that were categorized into five different species based on their ecophysiological variation and the divergence of their genomic sequences, of which four were novel. Surprisingly, one strain (represented by R-67174) was capable of methane oxidation, making this the first report on a methanotroph within a methylotrophic genus. Some claims were made in the past

© 2016 The Authors. Environmental Microbiology published by Society for Applied Microbiology and John Wiley & Sons Ltd., Environmental Microbiology, 18, 4523–4536
(Patt et al., 1974; 1976; Van Aken et al., 2004), but could never be independently verified (Dedysh et al., 2004a). Furthermore, its sole use of a sMMO and its marine origin as Alphaproteobacterial methanotroph makes strain R-67174 a unique discovery. *Methyloceanibacter* is the first genus with pMMO lacking methanotrophs retrieved from marine systems and only the third overall, next to *Methylorcella* and *Methyloferrula* (Dedysh et al., 2000; Vorobev et al., 2011), also phylogenetically the most closely related methanotrophs (Fig. 2; Supporting Information Fig. S2). Given the scattered phylogenetic distribution of the sMMOs among methanotrophs (Leahy et al., 2003), its soluble nature requiring fewer genes than the particulate form and its promiscuity (Jiang et al., 2010), it is very plausible that horizontal gene transfer (HGT) is responsible for the spread of the trait. Trait acquisition should enable recipients to colonize a wider range of habitats than possible with the pMMO alone (Leahy et al., 2003) or without any MMO. Nevertheless, to date no hard evidence or experimental data for HGT of sMMO has been reported. We found a deviation in GC content of *mmoXYBZCRG* (56%) compared to the average GC content of the genome (64%) in R-67174, which might point to a recent acquisition, but the gene cluster was completely flanked by hypothetical proteins and its immediate genome environment lacked actual remaining traces of HGT. As the sMMO machinery is the sole distinctive factor separating methanotrophs from other methylotrophs, the occurrence of methanotrophs within strict methylotrophic clades is most likely widespread but problematic to observe. Liquid extinction cultures under methane headspace, as in this study, might consist of a population of genotypically distinct con-generics or conspecifics not easily differentiated at morphological, physiological or genomic levels. Once transferred to solid media under methane headspace, the non-methane oxidizing methylotrophs are lost. All four pMMO lacking methanotrophs (*Methylorcella sylvestris*, *M. tundrae*, *M. palustris* and *Methyloferrula* *stellata*) belong to the Alphaproteobacteria, with R-67174 being the first isolated from a marine environment. Its isolation is not trivial as currently only eight marine methanotrophs are available in culture, *Methylomonas pelagicum* (Sieburth et al., 1987), *Methylbacter marinus* (Lidstrom, 1988), *Methylomonas* *japanense* (Fuse et al., 1998), *Methylophilus methanica* (Boden et al., 2011), *Methylomarinum vadi* (Hirayama et al., 2013), *Methylocaldum marinus* (Takeuchi et al., 2014b), *Methylolprofunds sedimenti* (Tavormina et al., 2015) and *Methylomarinovum calidicurali* (Hirayama et al., 2014), all of which are Gammaproteobacterial MOBs. Only three of them contain sMMO in addition to the pMMO (Fuse et al., 1998; Boden et al., 2011; Takeuchi et al., 2014b). The availability of marine methanotrophs *ex situ* clearly reflects the in situ situation, where Alphaproteobacterial MOBs have a widespread environmental distribution (Rockne and Strand, 2003; Rahman et al., 2011) but Gammaproteobacterial MOBs are numerically dominant in marine systems.

Although very closely related, genomic analysis, supported by ecophysiological analysis suggests the five *Methyloceanibacter* strains might occupy distinct ecological niches and/or potentially adhere to different life strategies, as evidenced by their differential kinetics of the methanol metabolism, nitrogen preferences, alternative carbon source utilization and optima for temperature, salt and pH. On example is the potential of R-67174 to use methane as sole source of carbon and energy. Acquisition of the methane oxidation capacity might give R-67174 a competitive advantage under methanol limitation. Like *Methylorcella* and *Methyloferrula* (Dedysh et al., 2004b; Vorobev et al., 2011), it also preferred growth on methanol over methane (evidenced by higher growth rate and shorter lag phase), which now seems characteristic for pMMO-lacking methanotrophs. Therefore, R-67174 might behave as a methylotroph in situ, as stable isotope probing already revealed *Methylorcella* spp. cross-feeding on the excreted products of other methanotrophs rather than oxidizing methane as a primary carbon source (C. Murrell, personal communication). In addition, methane oxidation can bestow R-67174 with the benefit of receiving second-ary metabolites like vitamins or growth promoting factors from co-existing microorganisms in return for ‘leaking’ methane-derived carbon compounds (Iguchi et al., 2011). Another example concerns the capacity to fixate nitrogen or assimilate nitrate. Both processes were found to be mutually exclusive in the *Methyloceanibacter* strains and would therefore ensure assimilation of alternative nitrogen sources under ammonium limitation. Based on our observations, indicating the divergence of their genomic sequences and their ecophysiology, the *Methyloceanibacter* strains can be categorized into five different ecotypes (Fig. 4). Wide ecotype variation among methylotrophs seems widespread. For example ecotypes have been identified among *Methylophilaceae* isolated from Lake Washington; these were characterized by differential responses to specific C1 stimuli (Beck et al., 2014), environmental adaptation strategies (Vorobev et al., 2013) and nitrate removal potential (assimilatory versus respiratory nitrate reduction) (Beck et al., 2014). Noteworthy is that ecological population boundaries frequently occur at deep phylogenetic levels (Johnson et al., 2006; Hunt et al., 2008; Pittera et al., 2014; Salt et al., 2015), which might preclude meta-omics approaches from uncovering essential trait differences among closely related strains with identical biomarker sequences. This deep-phylogenetic trait separation has already been demonstrated for the nitrogen metabolism of terrestrial methanotrophic *Methylomonas* strains (Hoefman et al., 2014). The organisms obtained in this study provide novel experimental models...
for studying the complexity and function of the microbial community active in methyloholtry.

The physiological and genomic data presented here helped to define strain variation within methylothermic bacteria and to disentangle the phylogenetic levels at which environmental variables influence marine methanotrophy and methyloholtry. Besides carbon metabolism, nitrogen cycling is confirmed to play a fundamental role in shaping methylothermic populations and salinity preferences will determine the localization of specific Methyloceanibacter strains in more coastal areas. The diverse metabolic features demonstrated here among only a small set of closely related methylothrophs, relative to the great genetic diversity revealed by ongoing metagenomic surveys, underlines the need for ongoing efforts in obtaining marine representatives ex situ. A change in isolation strategy targeting marine methanotrophs to broad screening of methanol-grown cultures will also aid to find more pMMO-lacking methanotrophs.

Description of Methyloceanibacter methanicus sp. nov.

Type strain: R-67174, LMG 29429

Etymology. N. L. neut. n. methanum, methane; L. masc. suff. -icus, adjectival forming suffix used with the sense of pertaining to; N.L. masc. adj. methanicus, related to or associated with methane.

Locality. Isolated from marine sediment in the North Sea at the station ‘Vlakte van de Raan’ (N 51.449166 E 3.237166)

Properties. Gram-negative, non-motile rods, liquid cultures form small microcolonies. Cells grow optimally at 18–37°C and pH 6.3–9 but requires NaCl at 3–5%. Grows aerobically on methane using a soluble methane monoxygenase but prefers methanol. Grows better with carbon dioxide added to headspace. Also grows using alternative carbon sources ethanol, acetate, formate and dimethylcarbonate. Capable of using ammonium and nitrate as inorganic nitrogen sources. The G + C content of the type strain is 64.5 mol%.

Description of Methyloceanibacter stevinii sp. nov.

Type strain: R-67177, LMG 29432

Etymology. L. n. margo, edge, margin; L. masc. suff. -alis, suffix denoting pertaining to; N.L. masc. adj. marginalis, referring to cells stick to the edge of the recipient in liquid culture.

Locality. Isolated from marine sediment in the North Sea at the station Hinderbanken (N 51.75 E 2.7)

Properties. Gram-negative, non-motile rods, liquid cultures grow attached to the side of the recipient and form flocks. Cells grow at 18–37°C, pH 6.3–9 and 0–5% NaCl. Grows aerobically on methanol. Also grows using alternative carbon sources ethanol, acetate, formate and dimethylcarbonate. Capable of using ammonium and nitrate as inorganic nitrogen sources. The G + C content of the type strain is 63.5 mol%.

Description of Methyloceanibacter marginalis sp. nov.

Type strain: R-67175, LMG 29431

Etymology. N. L. prep. super, above, on top; N.L. v. facere, to produce by growth; superactus, referring to high maximal cell densities.

Locality. Isolated from marine sediment in the North Sea at the station Hinderbanken (N 51.75 E 2.7)

Properties. Gram-negative, non-motile rods. Cells grow optimally at 18–28°C and pH 6.3–7.8 but requires 3% NaCl. Grows aerobically on methanol. Also grows using alternative carbon sources ethanol, formate and dimethylcarbonate. Capable of using ammonium and nitrate as inorganic nitrogen sources. The G + C content of the type strain is 64.0 mol%.

Experimental procedures

Sampling, enrichment and isolation

Marine surface sediments were collected in 2012 at two different stations in the Belgian North Sea, W04 (Vlakte van de Raan, N 51.449166 E 3.237166) and W09 (Hinderbanken, N 51.75 E 2.7), and used as inocula for enrichments. Initial enrichments were performed using media mimicking the in-situ nutrient conditions, based on in-situ concentrations measured periodically by the Belgian Marine Datacenter (http://www.mumm.ac.be/datacentre/) over the last 24 years. Phosphate concentrations were adjusted to the Redfield ratio (N/P: 16/1) (Cleveland and Liptzin, 2007) as data for phosphate was unavailable. Media composition was as follows: 25 μM KNO3, 0.5 μM NaNO2, 10 μM NH4Cl, 4 μM KH2PO4, 1 μM CuSO4·5H2O, 30 μM FeNaEDTA for W04; 5 μM KNO3, 0.3 μM NaNO2, 3 μM NH4Cl, 1.5 μM KH2PO4, 1 μM CuSO4·5H2O, 10 μM FeNaEDTA for W09. All media were prepared with aged seawater, collected at three meter depth.
from the sampling point. Enrichments were incubated at 20°C, shaking at 100 rpm and a headspace composition of 20:80 v/v methane/air.

After methane oxidation was observed and dense culture developed, the enrichments underwent an extinction culturing in NaCl-dANMS media (Holmes et al., 1995) supplemented with 1 mM KH₂PO₄, 500 µM NH₄Cl, 500 µM KNO₃, 1 µM CuSO₄·5H₂O, 40 µM FeNaEDTA, 100 nM of the lanthanides LaCl₃, CeCl₃·7H₂O, NdCl₃·6H₂O, PrCl₃ and 5 mM HEPES at a final pH of 7.8. Highest dilutions showing growth were transferred and underwent numerous subcultivations over a period of three years. Repeated subcultivations were not sufficient to purify the methane-oxidizing bacteria but resulted in a stable MOB-heterotroph community. Isolation of the strains was performed by plating on the growth medium solidified with Gelzan (1% w/v) and supplemented with 0.5% methanol. After several months of incubation small white colonies formed on the highest dilution plates. These were picked and placed in 5 mL liquid medium containing 0.5% methanol as sole carbon source. Picked colonies were identified using partial 16S rRNA gene sequences, as described previously (Heylen et al., 2006), and only isolates affiliated with *Methyloceanibacter* were retained. Purity was checked routinely through (i) microscopic evaluation and (ii) plating on 1/10 Trypticase Soy agar (TSA) under air atmosphere.

**Genotyping and next generation sequencing**

Genomic DNA was obtained by using Guanidium-thiocyanate-EDTA-sarkosyl for the enrichment cultures (Pitcher et al., 1989) or hexadecltrimethylammonium bromide (CTAB) for the pure cultures (Cleenwerck et al., 2009). DNA quality and quantity were checked on agarose gel and with Qubit Fluorometric Quantitation.

Pure cultures were typed by performing (GTG)₅ and Box rep-PCR fingerprinting as previously described (Heyman, 2005). Random shotgun sequencing of pure and enrichment cultures were done using the IonTorre PGM as described previously (Russ et al., 2014). Analysis of reads was performed using SPAdes genome assembler v3.5.0 (Bankevich et al., 2012) and CLC genomics workbench v7.0.4 (CLCbio, Denmark). The reads were length and quality score trimmed and used for *de novo* assembly. Contig binning of metagenomes from enrichment cultures was done by comparing GC content to sequencing depth and resulted in one and two draft genomes for enrichment W04 and W09 respectively. The Rapid Annotation Subsystem Technology (RAST) server was used for functional annotation and metabolic reconstruction of the (meta)genomes (Aziz et al., 2008; Overbeek et al., 2014). The classic RAST annotation scheme was selected using RAST gene caller which allowed automatic error fixing, frameshift correction and the backfilling of gaps. Assigned functions were verified with PSI-BLAST (Altschul, 1997). Missing genes were searched for in the genome with pBLAST using homologous amino acid sequences from the closely related organisms.

**Ecophysiology**

Growth of the different strains in different culture conditions was assessed in batch cultures (5 mL) by varying carbon source, nitrogen source, temperature, salinity and pH. All strains were grown at 28°C on NaCl-dANMS media (Holmes et al., 1995), i.e. dANMS supplemented with 3% NaCl, containing a concentration of 1 µM CuSO₄·5H₂O, 1 mM KH₂PO₄, 2 mM KNO₃, 2 mM NH₄Cl, 40 µM FeNaEDTA, 100 nM of the lanthanides LaCl₃, CeCl₃·7H₂O, NdCl₃·6H₂O, PrCl₃ and 5 mM HEPES, unless indicated otherwise. Methanol (1% v/v) was used as the sole carbon and energy source. Each growth condition was tested in triplicate. Utilization of the following alternative carbon sources (0.03%) was evaluated by monitoring growth in media without methanol: tryptic soy broth, acetate, acetate, formate, methylamine, dimethyl sulfoxide, dimethylcarbonate, formamide, ethanol, and no carbon source as negative control. Utilization of nitrate, ammonium was tested at concentrations of 0.5 mM, 1 mM, 2 mM, 5 mM and 10 mM. Alternatively yeast extract (0.03% w/v) was added to test as nitrogen source. The ability to fix nitrogen was assessed by evaluating growth in nitrogen free medium with 1% methanol under atmospheric concentrations of oxygen (20.94% O₂). Nitrous oxide production was tested for the different nitrate and ammonium concentrations by measuring headspace composition after 6 weeks growth. Salt tolerance (tested at 0%, 3%, 5% and 10% NaCl v/v spiked), pH range (tested at 5.8, 6.3, 6.8, 7.3, 7.8, 8.5, 9, 10 and 11) and temperature range (10°C, 18°C, 28°C, 37°C, 45°C and 52°C) were also determined.

**Growth kinetics on methane and methanol**

Cells harvested from mid-exponentially grown cultures were used as inoculum to start methane and methanol growth curves. Cells were washed twice with fresh carbon free medium and inoculated to a final starting OD₆₀₀ of 0.01. Methane oxidation was tested in 15 mL serum vials, containing 2.5 mL dANMS medium supplemented with 3% NaCl and 1% methanol. Based on initial tests, methane oxidation by strain R-67174 was clearly inhibited partially or completely by black non halogenated butyl rubber stoppers (Niemann et al., 2015). As such, vials were capped with grey halogenated Chlorobutyl stoppers (VWR® Chlorobutyl Serum and Lyophilization Stoppers) and incubated at 28°C, by shaking at 100 rpm and a headspace composition of either 20:80 v/v methane/air, 5:20:75 carbon dioxide/methane/air or 5:95 carbon dioxide/air. Per time point headspace composition analysis and biomass determination of these three serum vials were analyzed, which were subsequently discarded from the experiment. Because of attached cell growth to the serum vials glass by strain R-67177, cell flocks were disrupted with a manual glass homogenizer before biomass determination.

**Carbon source preference and sMMO activity assay**

Preferential use of methane or methanol as carbon source was tested using mid-exponentially grown cells as inoculum at a starting OD₆₀₀ of 0.01 in 200 mL dANMS medium in 1L bottles. Medium was spiked with methanol (v/v) to a final concentration of 1% under a headspace composition of 5:20:75 carbon dioxide/methane/air. Subsequently growth and methane were monitored over time in all six replicates. As negative control sterile medium was used and incubated under the same conditions. Qualitative sMMO expression was
tested by the naphthalene oxidation assay in liquid cultures (Brusseau et al., 1999). Naphthol inoculated cultures and methanone grown cultures were used as positive control. Quantitative sMMO activity assay was performed as described previously (Nyerges and Stein, 2009). In short, 10⁸ cells of mid-exponentially grown methanol fed cultures were harvested and washed twice in HEPES buffer (10 mM, pH 7.8), suspended in 1 mL HEPES buffer and placed into 60 mL glass vials sealed with grey butyl rubber stoppers and aluminum crimp seals. Methane and carbon dioxide were added to a final concentration of 5:20:75 carbon dioxide/methane/air, vials were incubated shaken (100 rpm) at 28°C and the headspace was sampled every hour during 5h and after 24h. Negative controls consisted of heat killed cells incubated under identical conditions. Three replicates were assayed per sample per time point.

**Analytical methods**

Growth was monitored over time by optical density at 600 nm using a Spectramax plus 384 spectrophotometer (Molecular devices). Mid-exponentially grown cells were used to correlate biomass to cell counts using live/dead flow cytometry as described previously (Van Nevel et al., 2013). Concentrations of CH₄, O₂ and carbon dioxide were measured with a Compact GC (Global Analyzer Solutions, Belgium), equipped with one channel connected to a flame ionization detector and two channels connected to a thermal conductivity detector. Values were converted to μmol/L for methane, oxygen and carbon dioxide by compensating for change in gas pressure (measured with an Infield 7 pressure meter, UMS, Germany) and taking the solubility of the gases into account. Methanol was analyzed using a 930 Compact IC Flex (Metrohm, Switzerland) ion chromatography system. Separation occurred at 35°C on a Metrosep Carb 2 (250/4.0) column behind a Metrosep Trap 1 100/4.0 guard column. The eluent was 20 mM NaOH at a flow rate of 0.8 mL min⁻¹. An IC amperometric detector (cycle: 300 ms 0.65V, 50 ms 0.55 V, 200 ms –0.1V detection during 200–300 ms of each cycle) was used for detection of eluted components. The sample aspiration needle was cleaned with acetone between each analysis. The lower limit of quantification was 79.2 mg L⁻¹. Standards and controls were regularly used for calibration of the signals.

**Data analyses**

A parametric fit of growth data for each replicate was made using non-linear least squares fitting with four different parametric models, i.e. the Gompertz, Exponential Gompertz, Richards and logistic growth curve models (Zwietering et al., 1990). The model with the best Akaike Information Criterion is returned. Non-parametric fitting using lowess is used to perform initial parameter estimation. Generation time was calculated based on specific growth rate. For significance testing, one-way ANOVA with Tukey HSD contrasts was run if the data was homoscedastic (Modified Levene’s test) and the residuals normally distributed (Shapiro-Wilk normality test). If the homoscedasticity assumption was not met, Weighted least squares was performed with Tukey simultaneous relative contrast effects for general linear hypotheses with a single-step method (Hothorn et al., 2008), while if the normality assumption was not met non-parametric multiple contrast effects were used for the multiple comparison (Konietschke et al., 2015).

**Accession numbers**

The Whole Genome Shotgun projects of *Methylococcanibacter* sp. R-67174, R-67175, R-67176 and R-67177 have been deposited at DDBJ/EMBL/GenBank under the accession numbers LPWG00000000, LPWF00000000, LPWE00000000 and LPWD00000000 respectively. The versions described in this paper are the first versions. The reads of the metagenomes of both enrichment cultures are available in the SRA database (study accession number SRP068992).

**Acknowledgements**

The authors thank André Catttijssse of the Flanders Marine Institute (VLIZ) and the captain and crew of the research vessel Zeelieeuw and Simon Stevin for the logistic and practical support during the different sampling surveys. Special thanks to C. Dumolin for assistance with flow cytometry analysis, B. Tytgat for his assistance with R, D. Speith for his help with metagenome data analyses and J. Arends for methanol analyses. They also thank C. Dumolin, F. Beeckman, J. Wille and H. Declerey for their much appreciated help in maintaining enrichment and pure cultures and performing the sampling campaigns.

This work was funded by Ghent University (BOF09/GOA/005). K. Heylen was funded by the Fund for Scientific Research Flanders for a position as a postdoctoral fellow (FWO11/PDO/084 and FWO15/PDOH1/084). B. Vekeman by the Agency for Innovation by Science and Technology (IWT/111108), F.-M. Kerckhof by the Inter-University Attraction Pole (IUAP) ‘µ-manager’ (the Belgian Science Policy P7/25) and Geert Cremers by SIAM Gravitation Grant 24002002 (Netherlands Organisation for Scientific Research). HJM Op den Camp gratefully acknowledges funding by ERC grant 669371 (VOLCANO).

Fig. S1. Representatives of each Methyloeanibacter genotype based on (GTG)₅ (A) and Box (B) repetitive sequence based (Rep) PCR fingerprinting. Forty-one isolates assigned to the genus Methyloceanibacter based on partial 16S rRNA gene sequence similarity were grouped into four clusters, all distinct from Methyloceanibacter caenitepidi Gela4T, with both techniques. Dendrograms were created using Pearson product moment correlation coefficient and UPQMA using BioNumerics 7.5.

Fig. S2. Phylogenetic Maximum Likelihood showing the affiliation of the novel Methyloceanibacter spp. based on the 16S rRNA gene. The evolutionary history was inferred by using the Maximum Likelihood method based on the Tamura-Nei model [1] using 1322 nucleotide positions. The tree with the highest log likelihood (−9625.9027) is shown. Bootstrap values (1000 replicates) higher than 70 are shown next to the branches. A discrete Gamma distribution was used to model evolutionary rate differences among sites (5 categories (+G, parameter = 0.5937)). The tree is drawn to scale, with branch lengths measured in the number of substitutions per site. Alignment was performed using SILVA Incremental Aligner [2] and evolutionary analyses were conducted in MEGA6 [3].

Fig. S3. Physical map of genome environment of sMMO operon in R-67174, closely related and other
methanotrophs. Homologs are depicted in identical colors. ORF of hypothetical proteins are given as white arrows. ME, ORF for mobile element. Drawn to scale.

**Fig. S4.** Growth (•) and methane oxidation (■) by R-67174 over time when both methane and methanol are provided as carbon source ($n = 6$). No methane was consumed and lag phase, specific growth rate and maximal cell density was not different from that on methanol alone (see Table 1). Growth on methanol (1%) or methane (5.4 mM) as sole carbon source are given for comparison as grey dotted and dashed lines respectively. All growth experiments were performed with addition of carbon dioxide.

**Fig. S5.** Phylogenetic Maximum Likelihood showing the affiliation of the methanol dehydrogenases. Representatives of MxaF, five Xox types, and nine clades of other type I and II alcohol dehydrogenase quinoproteins were chosen based on Keltjens et al. (2014) [4]. Sequences from this study are given in bold. For further explanation on subgrouping of XoxF1, see text.
