Cell Metabolism

Glutaminolysis and Fumarate Accumulation Integrate Immunometabolic and Epigenetic Programs in Trained Immunity

Graphical Abstract

Highlights

- Cellular metabolism undergoes major shifts in β-glucan-trained monocytes
- Glucose, glutamine, and cholesterol metabolism are crucial in trained immunity
- Accumulation of fumarate is essential for epigenetic changes in trained immunity

In Brief

As part of the IHEC consortium, Arts et al. dissect how metabolic pathways regulate epigenetic rewiring in trained immunity (innate immune memory). They show that glycolysis, glutaminolysis, and cholesterol metabolism are indispensable in trained monocytes and link fumarate accumulation to epigenetic changes. SUMMARY

Induction of trained immunity (innate immune memory) is mediated by activation of immune and metabolic pathways that result in epigenetic rewiring of cellular functional programs. Through network-level integration of transcriptomics and metabolomics data, we identify glycolysis, glutaminolysis, and the cholesterol synthesis pathway as indispensable for the induction of trained immunity by β-glucan in monocytes. Accumulation of fumarate, due to glutamine replenishment of the TCA cycle, integrates immune and metabolic circuits to induce monocyte epigenetic reprogramming by inhibiting KDM5 histone demethylases. Furthermore, fumarate itself induced an epigenetic program similar to β-glucan-induced trained immunity. In line with this, inhibition of glutaminolysis and cholesterol synthesis in mice reduced the induction of trained immunity by β-glucan. Identification of the metabolic pathways leading to induction of trained immunity contributes to our understanding of innate immune memory and opens new therapeutic avenues.

INTRODUCTION

Recent studies demonstrated that certain infections and vaccinations induce innate immune memory (also termed trained immunity; Netea et al., 2016) in monocytes, macrophages, and natural killer cells, resulting in non-specific protection against reinfection (Quintin et al., 2012; Sun et al., 2009). The biological relevance of innate immune memory is demonstrated by its broad presence in nature, with studies in organisms as diverse as plants, insects, cephalopods, and mammals reporting its impact for resistance to infections (Fu and Dong, 2013; Kurtz, 2005; Netea et al., 2011). Many of the studies reporting adaptive characteristics embedded in innate immune responses predate the modern era of molecular biology: the lack of understanding the molecular mechanisms underlying their effects impaired, however, the capacity to fully understand the importance of this process. This situation has changed profoundly over the last few years, when several studies demonstrated that epigenetic reprogramming forms the basis of innate immune memory in both plants (Muthamilarasan and Prasad, 2013; Shah et al., 2014) and mammals (Kleinnijenhuis et al., 2012; O’Sullivan et al., 2015; Quintin et al., 2012; Saeed et al., 2014).

Genome-wide changes in histone modifications have been shown to underlie trained immunity in monocytes, but the molecular mechanisms linking the immunological signals induced by microbial stimuli or vaccines to the epigenetic changes have not been deciphered. Changes in cellular metabolism, with a shift from oxidative phosphorylation to aerobic glycolysis (Warburg effect), are crucial for the induction of β-glucan-induced trained immunity (Cheng et al., 2014). Interestingly, increasing evidence links cellular metabolism to the regulation of gene transcription, as several metabolites from glycolysis and the TCA cycle have been shown to act as cofactors for epigenetic writers and erasers such as DNA and histone methyltransferases and...
demethylases and histone acetyltransferases and deacetylases (Donohoe and Bultman, 2012; Hirschey et al., 2015). These circuits have important functional consequences based on how cells use metabolic substrates: for example, type 1 inflammatory macrophages (M1IFNγ) rely on increased glycolysis (Mills and O’Neill, 2015; Pearce et al., 2013; Tan et al., 2015), whereas tolerant macrophages (M2IL-4) rely on oxidative phosphorylation and β-oxidation (Mills and O’Neill, 2015; Van den Bossche et al., 2015). Interestingly, not only glucose metabolism, but also other metabolic pathways play important roles in reprogramming and polarizing cells (Cheng et al., 2016; Donohoe and Bultman, 2012; Hirschey et al., 2015).

Based on this growing body of evidence, we hypothesized that changes in cellular metabolism in trained immunity not only reflect enhanced energetic needs, but also connect with immune pathways and epigenetic reprogramming, through the accumulation of specific metabolites modulating epigenetic processes that impact the functional program of the cell. We combined transcriptomic, metabolic, and epigenomic studies to identify important metabolic processes activated in β-glucan-trained monocytes. We validated the role of these processes in induction of trained immunity, identifying an important function for glutamine metabolism and fumarate accumulation. The importance of these processes was also demonstrated in vivo models of trained immunity.

RESULTS

Cellular Metabolic Pathways in Monocytes during Induction of Trained Immunity
β-glucan and bacterial lipopolysaccharide (LPS) induce different long-term functional programs in monocytes and macrophages; i.e., enhanced function and tolerance, respectively; with transcriptomic and epigenomic analyses revealing major differences in glucose metabolism pathways (Cheng et al., 2014; Saeed et al., 2014). To elucidate whether additional metabolic pathways are differentially expressed between trained and tolerant cells, RNA-sequencing (seq) expression data at different time points after stimulation with β-glucan and LPS were analyzed for metabolic pathways and full intracellular metabolome assessment was performed. We used the previously described in vitro model of trained immunity (Cheng et al., 2014) in which purified monocytes are stimulated for 24 hr with RPMI, β-glucan, or LPS, after which cells are washed and rested for 5 days in culture medium, followed by a second 24 hr stimulation with either medium or LPS (Figure S1). Distinct RNA expression patterns between β-glucan-trained and non-trained (RPMI) cells were visible after 24 hr of stimulation, with the largest differences observed at the day 6 time point in LPS-treated cells (Figure 1A; Table S1). Metabolome data of trained and tolerant cells showed that at early time points (4 hr and 24 hr after stimulation), only small differences existed between the three conditions (RPMI, LPS, β-glucan). On day 6, however, the intracellular metabolome of β-glucan-trained cells was clearly different from the RPMI and LPS-treated cells, with major differences observed in TCA cycle metabolites, fatty acid metabolism, and other pathways (Figures 1B and S1; Tables S2 and S3). Altogether, these data indicate that the majority of transcriptional changes associated with metabolic pathways occur early (24 hr) in β-glucan-exposed cells and precede the metabolic phenotype observed in fully differentiated β-glucan-trained macrophages on day 6.

Integration of the transcriptome and metabolome data in a network-level context revealed an upregulation of several major metabolic pathways in β-glucan-trained macrophages, including glycolysis, pentose phosphate pathway (PPP), and cholesterol metabolism (Figures 1C and S1). Interestingly, several important TCA metabolites were strongly increased, such as succinate, malate, and fumarate, as well as 2-hydroxyglutarate, leading us to hypothesize that TCA metabolites were being replenished through glutaminolysis (Figures 1C and S1).

Glycolysis, but Not PPP, Is an Essential Metabolic Pathway in Trained Immunity
Glucose consumption is increased in β-glucan-trained macrophages (Cheng et al., 2014), and our metabolome analysis supports an increase in glycolysis. To obtain further insight into the major accumulated products of glucose metabolism, we performed NMR experiments with 13C-labeled glucose in trained monocytes. First, glucose was converted into lactate, validating the upregulation of glycolysis with concomitant lactate production in β-glucan-trained monocytes that we reported previously (Cheng et al., 2014). In addition, labeled purines were also detected, showing the activation of the PPP (Figures 2A and S2). In contrast, neither 13C-labeled metabolites of the TCA cycle were detected after incubation of trained monocytes with 13C-labeled glucose, nor 3-13C lactate, indicating that the non-oxidative branch from the PPP back to glycolysis was inactive (Figures 2A and S2).

As glucose can be metabolized by aerobic glycolysis and PPP, we assessed which of these pathways was important for induction of trained immunity. Inhibition of mTOR and glycolytic flux by rapamycin inhibited monocyte training, as previously shown (Cheng et al., 2014), whereas inhibition of the oxidative
branch of the PPP by 6-aminonicotinamide (6-AN) had no effect (Figure 2B). The increase in cytokine production by β-glucan-induced trained immunity is accompanied by epigenetic changes, including an increase of H3K4 trimethylation (H3K4me3) at promoter sites of inflammatory genes (Saeed et al., 2014). Consistent with similar observations in cytokine production, epigenetic changes in H3K4me3 induced by β-glucan at the promoter sites of IL6 and TNFA were abolished by rapamycin, but not by 6-AN (Figures 2B and S3). Thus, whereas glycolysis is central for induction of trained immunity, inhibition of PPP does not have a direct effect on increased cytokine production by trained monocytes.

Metformin activates AMPK and inhibits mTOR activity (Figure S3) (Cheng et al., 2016). We have previously shown that inhibition of the mTOR pathway that controls glucose metabolism by metformin counteracts the induction of trained immunity by β-glucan in mice (Cheng et al., 2014). We now also show that metformin inhibits lactate production, 5 days after β-glucan training (Figure S3). To assess whether metformin has a similar effect in vivo in humans, we initiated a proof-of-principle clinical trial in which healthy volunteers received an incremental dose of metformin for 6 days (up to 1,000 mg twice daily on day 6). In line with the in vitro and murine experimental data, in vivo administration of metformin in humans decreased the ex-vivo β-glucan-induced training of circulating monocytes, which was accompanied by a lower capacity to mount glycolysis and release lactate (Figure 2C). When the study participants stopped taking metformin, the capacity of monocytes to undergo β-glucan training was fully restored (day 9 and 20), thereby confirming the importance of glucose metabolism changes for inducing trained immunity in humans (Figure 2C).

Glutamine and Cholesterol Metabolism Are Important Metabolic Pathways in Trained Immunity

In addition to glycolysis and PPP, glutamine metabolism, cholesterol, and fatty acid synthesis pathways were also upregulated after β-glucan training. Glutamine metabolism has been shown to play an important role in immune activation (Li et al., 2007; Roth, 2008; Sikalidis, 2015). Incubation of trained monocytes with 13C-labeled glutamine resulted in increased production of glutamate, a substrate that can replenish the TCA cycle (Figures 3A and S2). Although no labeled succinate, fumarate, or malate were identified due to their relatively low concentrations and the limited sensitivity of the assay, we were able to measure increases in these TCA cycle metabolites using classical biochemical methods (Figures S1 and S4). Interestingly, no labeled lactate was detected, suggesting that glutamine is not a source of pyruvate for lactic fermentation (Figures 3A and S2). This interpretation was supported by the near 1:2 molar ratio of glucose:lactate observed in the 13C-glucose experiment, suggesting that glucose is the sole source of lactate; the ratio would have been lower if also other sources of lactate would have been used.

Aspartic acid was also consumed in large amounts from the medium, indicating that metabolism of amino acids other than glutamine may also be involved in trained immunity (Figure S4). In line with this notion, production of 2-hydroxyglutarate from α-ketoglutarate was also significantly increased, just as methionine (Figure S1). Finally, in addition to the well-known pathway in which glutamate enters the TCA cycle via α-ketoglutarate, glutamate catabolism also enters the TCA cycle via succinate semialdehyde metabolism (Figure 1C).

In an additional set of experiments, we sought to establish the role of glutamine, fatty acid, and cholesterol synthesis in trained immunity by adding inhibitors of these pathways (BPTES, cerulenin, and fluvastatin, respectively) to the in vitro trained immunity model. Inhibition of glutaminolysis or cholesterol synthesis inhibited trained immunity, whereas blockade of fatty acid synthesis had no effect (Figures 3B and S3). In line with these results, H3K4me3 was downregulated by inhibition of either glutaminolysis or cholesterol synthesis (Figure 3B). We next tested the relevance of these pathways in an in vivo model of trained immunity by assessing the effects of BPTES that inhibits glutaminolysis, and atorvastatin, which inhibit the rate-limiting enzyme in cholesterol synthases HMG-CoA-reductase. Mice were treated with 1 mg of β-glucan or vehicle control intraperitoneally, followed 1 week later by an injection of 10 μg LPS. At 4 hr after the LPS challenge, induction of cytokine synthesis was measured by ELISA in the circulating blood. We found that LPS induced a significantly higher IL-1β concentration in plasma of β-glucan-trained mice than of controls (Figure 3C), as previously reported (Quintin et al., 2012). Importantly, when glutaminolysis was inhibited by BPTES or cholesterol synthesis was inhibited by atorvastatin, trained immunity, measured by IL-1β production, was significantly downregulated (Figure 3C). The plasma concentrations of TNF at this time point after LPS injection were low and not different between the various conditions. Together, these data show that glutaminolysis and the cholesterol synthesis pathway are two metabolic pathways that, in addition to glycolysis, are essential for the increased cytokine production and epigenetic changes observed in β-glucan-induced trained immunity.

Fumarate Induces Epigenetic Changes and Trained Immunity

Analysis of the metabolome of trained monocytes showed that succinate, fumarate, and malate were strongly induced in these
A

cells (Figures 1 and S1). We first assessed whether any of these metabolites by themselves can induce trained immunity. Training of monocytes with fumarate on day 0 dose-dependently induced increased cytokine production upon restimulation on day 6, whereas malate and succinate did not induce this effect (Figure 4A). Inhibition of glycolysis or glutaminolysis by rapamycin or BPTES, respectively, both pathways that inhibit β-glucan-induced trained immunity, also decreased fumarate concentrations in trained monocytes (Figure 4B). In addition, fumarate induced H3K4me3 at the promoters of proinflammatory cytokines, as observed during induction of trained immunity by β-glucan (Figure 4C). Considering these effects, we performed a whole-genome assessment of the histone marks H3K4me3 and H3K27ac by chromatin immunoprecipitation (ChIP)-sequencing in fumarate and β-glucan-trained monocytes (Figure 4D). In total, 124 dynamic H3K4me3 regions (Figure 4E) and 332 dynamic H3K27ac regions (Figure 4F) were identified in fumarate-trained macrophages, with a log2 fold change >2.5 compared to non-trained macrophages (RPMI). By the same criteria, β-glucan exposure induced 2,688 dynamic H3K27ac changes (Figure S5), indicating that fumarate-induced chromatin remodeling recapitulates only a small fraction of the total trained epigenome. However, 95% of the genomic regions differentially regulated by fumarate were also differentially regulated by β-glucan (>1 log2 fold change). If for β-glucan a log2 fold change of >2 were being used, this would account for 63% of the regions. Genes associated with fumarate dynamic epigenetic regions were enriched in pathways involved in immune response and leukocyte migration (Figures 4E and 4F), consistent with previous reports in β-glucan-trained monocytes (Quintin et al., 2012; Saeed et al., 2014).

Citic acid cycle metabolites (e.g., fumarate and succinate) have previously been reported to regulate HIF1α stabilization by inhibiting hydroxylation and therefore stabilizing HIF1α (Koivunen et al., 2007; Tannahill et al., 2013). We first assessed whether fumarate inhibited HIF1α hydroxylation in our in vitro model. Incubation of human monocytes with fumarate for 2 hr inhibited HIF1α hydroxylation (Figure 5A), and HIF1α targets (Ke and Costa, 2006) were identified on a transcriptional level (Figure 5B). This provides a first mechanism of how fumarate could induce the observed phenotypical changes, but it does not explain the observed effects on histone modifications.

Therefore, given our finding that fumarate induces H3K4me3, we investigated whether it could induce transcription of methyltransferases. However, none of the detectable methyltransferases were differentially expressed between trained and non-trained samples (Figure S6). We therefore assessed whether the activity of the KDM5 family of histone demethylases, which are responsible for demethylation of H3K4 (Secombe and Eisenman, 2007), was different in β-glucan trained macrophages. As shown in Figure 5C, β-glucan training of monocytes resulted in decreased biological activity of KDM5 demethylases on day 6 after training, which corresponds to the time point with the highest intracellular fumarate concentrations (Figure S1), an effect that was not observed in LPS-induced immunotolerant macrophages (Figure 5C). Interestingly, a similar effect was observed at transcription level (Figure S6). We also assessed expression of KDM3a/JMJD1a (a H3K9 demethylase) and KDM6b/JMJD3 (a H3K27 demethylase), but these genes were not significantly influenced during induction of training (Figure S6). Finally, as ω-ketoglutarate is a known cofactor for lysine demethylases, whereas metabolites that have a comparable molecular structure to ω-ketoglutarate (e.g., fumarate or succinate) are natural antagonists (Lu et al., 2012), we also determined whether the effect of fumarate on KDM5 activity is influenced by ω-ketoglutarate. KDM5 activity was significantly inhibited by fumarate and that was restored by the addition of ω-ketoglutarate (Figure 5D). Also at the level of cytokine production, ω-ketoglutarate was able to partially counteract the training effect of fumarate (Figure 5E).

DISCUSSION

In this study, we provide the first mechanism linking stimulation of innate immune pathways with the induction of epigenetic and metabolic changes in trained immune cells. We show that training of monocytes with β-glucan induces a rewiring of cellular metabolism that modulates the epigenetic programming of metabolic genes. Glycolysis, glutaminolysis, and cholesterol synthesis are non-redundant metabolic pathways important for trained immunity in monocytes and macrophages. Among the detailed metabolite changes, we identify fumarate as a key metabolite that induces trained immunity (innate immune memory), an effect mediated at least partially by induction of histone modifications such as H3K4me3 and H3K27Ac.

The role of cellular metabolites acting as cofactors for epigenetic enzymes has only recently been revealed in several cell types and tissues (Donohoe and Bultman, 2012; Keating and El-Osta, 2015). By assessing the interaction between transcriptional and metabolic profiles, we identified several major metabolic pathways specifically activated in trained monocytes, compared with naive and tolerant cells. Glucose enters both glycolysis and PPP during activation of trained monocytes. Whereas glycolysis has been previously reported to be important for trained immunity (Cheng et al., 2014), very little is known regarding the role of the PPP in this process. Here, we validate several previous studies of the role of the mTOR pathway and glycolysis and extend them in a proof-of-principle clinical trial.
Figure 4. Fumarate-Induced Trained Immunity

(A) Human monocytes were stimulated for 24 hr with different concentrations of methyl-fumarate. At day 6, cells were restimulated for 24 hr with LPS and cytokine production was assessed. The data are shown as means ± SEM, n = 8, *p < 0.05, one-way ANOVA, and Dunnett’s post test.

(B) Human monocytes were trained with β-glucan in the presence or absence of metabolic inhibitors for 24 hr. On day 6, cells were lysed and intracellular fumarate concentrations were determined. The data are shown as means ± SEM, n = 9, *p < 0.05, **p < 0.01, and one-way ANOVA.

(C) Human monocytes were stimulated for 24 hr with 50 μM methyl-fumarate. At day 6, cells were fixed, chromatin was isolated, and H3K4me3 at the promoters of TNFA and IL6 were determined. The data are shown as means ± SEM, n = 5, *p < 0.05, and Wilcoxon signed-rank test.

(D) Experimental setup for the generation of fumarate-treated macrophages for epigenomic analysis.
By using metformin, an activator of AMP kinase and thus inhibitor of mTOR, in healthy volunteers, we demonstrate a role for the mTOR pathway in trained immunity in humans. This observation goes beyond answering a biological question, as metformin is a widely used drug in patients with type 2 diabetes (Singh, 2014). Indeed, its inhibition of trained immunity might have undesired consequences on antimicrobial host defense; on the other hand, it may represent a potential new drug to be employed in certain inflammatory diseases with excessive inflammation (Robey et al., 2015; Singhal et al., 2014; Tan et al., 2015). In contrast to glycolysis, the oxidative branch of PPP does not seem to have a major impact on trained immunity.

Using a systems biology approach, our analysis of intracellular metabolites of trained monocytes identified additional pathways that are involved in trained immunity (Figure 6). The metabolism of several amino acids was enhanced, including glutamine. Metabolism of glutamine into glutamate, α-ketoglutarate, and succinate semialdehyde provides substrates for the TCA cycle such as fumarate and succinate. Interestingly, fumarate itself induces trained immunity as well. Trained immunity induced by fumarate results in increased trimethylation of histones at H3K4, and interestingly also acetylation at H3K27, linking immune to DNA repair by inhibition of KDM2B histone demethylases (that is responsible for H3K4 demethylation) has been shown to be inhibited by fumarate (Lu et al., 2012; Xiao et al., 2012). Recently, locally produced fumarate has also been shown to play a role in DNA repair by inhibition of KDM2B histone demethylase activity, which resulted in enhanced H3K36me2 (Jiang et al., 2015). We now show that fumarate inhibits the bioactivity of KDM5s in our model of trained immunity and that α-ketoglutarate can counteract this effect. In addition to fumarate, the concentration of 2-hydroxyglutarate, which has similar antagonizing effects on α-ketoglutarate-dependent demethylases (Yang et al., 2012), is greatly increased in β-glucan-trained macrophages too (Figure S1). Therefore, 2-hydroxyglutarate may serve as another essential factor in modulating histone marks in trained immunity induced by β-glucan. Xiao et al. (2012) have previously shown that fumarate (and potentially 2-hydroxyglutarate) does not only affect histone demethylases, but also affect DNA demethylases. The effect of β-glucan training and metabolic alterations on DNA methylation is therefore an intriguing topic for future research. In addition to the effects of fumarate on epigenetic enzymes, fumarate also inhibits proteasomal degradation of HIF1α, an essential transcription factor in β-glucan-induced trained immunity (Cheng et al., 2014; Koivunen et al., 2007; Serra-Pérez et al., 2010). In this process, α-ketoglutarate is a cofactor for the hydroxylation necessary for HIF1α degradation; fumarate is a natural antagonist of this reaction, thereby stabilizing HIF1α.
In conclusion, we show that β-glucan-induced trained immunity in monocytes induces profound changes in cellular metabolism. The three most prominent metabolic pathways involved in trained immunity are glycolysis, glutaminolysis, and cholesterol synthesis, which are linked to enrichment in H3K4me3 that is essential for trained immunity by β-glucan. Finally, we provide proof-of-principle of metabolo-epigenomic circuits in innate immune memory by demonstrating an essential role for fumarate in modulating HIF1α degradation, histone methylation, and acetylation. The identification of the metabolic pathways contributing to induction of trained immunity improves understanding of innate immune memory and opens new therapeutic avenues.

EXPERIMENTAL PROCEDURES

Peripheral Blood Mononuclear Cell and Monocyte Isolation

Buffy coats from healthy donors were obtained after written informed consent (Sanquin Blood Bank, Nijmegen, the Netherlands). Peripheral blood mononuclear cell (PBMC) isolation was performed by elution of blood in pyrogen-free PBS and differential density centrifugation over Ficoll-Paque (GE Healthcare). Cells were washed twice in PBS. Training of adherent monocytes was performed as previously described (Quintin et al., 2012); see also below. Percoll isolation of monocytes was performed as previously described (Repnik et al., 2003). Briefly, 150 × 10⁶ PBMCs were layered on top of a hyper-osmotic Percoll solution (48.5% Percoll [Sigma-Aldrich], 41.5% sterile water (H2O), and 0.16 M filter-sterilized NaCl) and centrifuged for 15 min at 580 × g. The interphase layer was isolated and cells were washed with cold PBS. Cells were resuspended in RPMI culture medium (RPMI medium, Invitrogen) supplemented with 10 μg/mL gentamicin, 10 mM Glutamax, and 10 mM pyruvate, and counted. An extra purification step was added by adhering Percoll-isolated monocytes to polystyrene flat bottom plates (Corning) for 1 hr at 37°C; a washing step with warm PBS was then performed to yield maximal purity.

Monocyte Training and Inhibition Experiments

100 μL cells were added to flat bottom 96-well plates. After washing with warm PBS, monocytes were incubated with culture medium only as a negative control or 5 μg/mL of β-glucan, (β-1,3-(D)-glucan, kindly provided by Professor David Williams), 100 μM mono methyl-fumarate, or dimethyl-2-oxo-glutarate (Sigma) for 24 hr (in 10% pooled human serum). Cells were washed once with 200 μL warm PBS and incubated for 5 days in culture medium with 10% serum and medium was changed once. Cells were restimulated with 200 μL RPMI, Escherichia coli LPS (serotype 055:B5, Sigma-Aldrich), 10 ng/mL, or Pam3Cys (EMC Microcollections, L2000, 10 μg/mL). After 24 hr, supernatants were collected and stored at −20°C (see Figure S1). In some experiments, cells were preincubated (before β-glucan training) for 1 hr with 10 nM rapamycin (Sigma), 50 μM BPTES (Sigma), 2 μM/μL Geruline (Sigma), 100 μM 6-aminonicotinamide (Sigma), and 20 μM fluvastatin sodium hydroxide (Sigma). Concentrations were selected as being the highest non-cytotoxic concentrations.

Cytokine and Lactate Measurements

Cytokine production was determined in supernatants using commercial ELISA kits for TNF-α (R&D Systems) and IL-6 (Sanquin) following the instructions of the manufacturer. Lactate concentration was measured using a Lactate Fluorometric Assay Kit (BioVision).

High-Performance Liquid Chromatography and NMR

Amino acids were quantified by high-performance liquid chromatography (HPLC) in a Gilson UV/vis_155 detector (338 nm) after precolumn derivatization with ortho-phthalaldehyde (OPA) with methanol ≥ 99.9%, potassium borate 1 M pH = 9.5 and 2-mercaptoethanol ≥ 99.0% 1:5 (Sigma-Aldrich). Culture supernatants were filtered by Acrodisc 13 mm syringe filters with 0.2 μm supermembrane (Pall), Inorganic mobile phase pH = 7.8 was composed of Na2HPO4, 2H2O, 50 mM; propionic acid 250 mM (1:1) mixture (Merck) with acetonitrile HPLC grade in water (10:2:13). Organic mobile phase was composed by acetonitrile, methanol, and water (3:3:4) (HPLC grade, HiPerSolv Chromanorm, WVR Chemicals). All mobile phases for elution were degasified for 30 min previously to analysis. Amino acids were quantified using the Gilson Uniprot Software, version 5.11 accordingly to standard solutions were prepared in MilliQ water (Millipore).

For NMR spectroscopy, methanol/water extracts and cell culture supernatants were analyzed. The aqueous and chloroform extracts were dried in a SpeedVac Plus system. The aqueous extract was suspended in 600 μL D2O with 0.262 mM of TSP-d4 as chemical shift indicator and the organic extract in 600 μL CD3OCl. To 550 μL of cell culture media were added 50 μL D2O, with a TSP-d4 final concentration of 0.262 mM.

The samples were analyzed at 25°C by 1H-NMR and by 2D 13C-1H heteronuclear single quantum coherence (HSQC) spectroscopy in a UltrashieldTM 800 Plus (Bruker) operating at 800.33 MHz, equipped with a TXI-2H C/N-D (5 mm) probe. The 1H-NMR pulse sequence used has a NOESY-pressaturation (noesygpppr1d) with irradiation at the water frequency (ns 124, TD 64K, SW 20 ppm, d1 4 s, d8 0.01 s); while in the 13C-1H-HSQC was used the hsqcetgpsisp2 pulse sequence (ns 16, TD 512, TD2 2K, SW 16 ppm, SW1 165 ppm, d1 1 s). The chemical shifts in aqueous sample were referred to TSP, while the samples in chloroform-d were referred to the solvent signal.

Spectra were acquired and processed using TopSpin 3.2 software (Bruker); assignments were made by comparison with chemical shifts found in the literature for metabolic intermediates and Human Metabolome Database (http://www.hmdb.ca). The quantifications of the signals were performed by
integration of the peaks in the $^{1}H$-NMR spectra and of the volumes in the $^{13}C$-$^{1}H$-HSQC spectra, using the resonance due to the TSP as reference.

**Metabolite Measurements**

Cells were cultured as described above. At day 6, cells were detached from the plate with Versene (Life Technologies) and counted. At least one million cells were lysed in 60 μL 0.5% Triton-X in PBS. Metabolite concentrations were determined by commercial assay kits for Acetyl CoA, fumarate, glutamate, maltate, NADPH, and $\alpha$-ketoglutarate (all Sigma), following the instructions of the manufacturer.

**mRNA Extraction and RT-PCR**

Cells were cultured as described above, after 4 hr, 12 hr, and 24 hr for fumarate stimulation or after 6 days after β-glucan training. RNA was extracted by TRIzol (Life Technologies), according to the manufacturer’s instruction, and cDNA was synthesized using iScript reverse transcriptase (Invitrogen). Relative mRNA levels were determined using the Applied Biosciences StepOne PLUS and the SYBR Green method (Invitrogen). Values are expressed as fold increases in mRNA levels, relative to those in non-trained cells, with β-2-microglobulin or HPRT as housekeeping genes. Primers are listed in Table S4. RNA-sequencing was performed as described before (Saeed et al., 2014).

**Chromatin Immunoprecipitation**

10 x 10^6 monocytes were trained in vitro in 10 cm petri dishes (Greiner) in 10 mL medium volumes. Cells were isolated and trained as described above. After resting for 5 days in culture medium, the cells were detached from the plate with Versene and fixed in methanol–free 1% formaldehyde. Cells were then sonicated and immunoprecipitation was performed using antibodies against H3K4me3 (Diagenode). After ChIP, DNA was processed further for qPCR analysis using SYBR green. Samples were analyzed by a comparative Ct method in which myoglobin was used as a negative control and H2B as a positive control according to the manufacturer’s instructions. Primers are listed in Table S4.

**Metabolome Assessment**

Cells were cultured as described above. At 0 hr, 4 hr, 24 hr, and 6 days, cells were harvested and cell pellets were snap frozen and stored at −80°C until metabolite analysis. Measurement of metabolites was performed by liquid chromatography–tandem mass spectrometry (LC-MS). Polar metabolites were extracted in 80% methanol. Metabolic profiles were obtained using three LC-MS methods. Two separate hydrophilic interaction liquid chromatography (HILIC) methods were used to measure polar metabolites in positive and negative ionization mode MS, and one reversed phase method was used to profile lipids in the positive ion mode. Polar metabolites were profiled in the positive ion MS mode using an LC system comprising a 1200 Series Pump (Agilent Technologies) and an HTS PAL Autosampler (Leap Technologies) that was coupled to a 4000 QTRAP mass spectrometer (AB SCIEX) equipped with an electrospray ionization source. Samples were prepared by drying 100 μL of cell extracts under nitrogen and resuspending the residue in 100 mL of 10/67/4.22/4.02 v/v/v/v water/acetonitrile/methanol/formic acid containing stable-isotope labeled internal standards (valine-d8, Sigma-Aldrich; and phenylalanine-d8, Cambridge Isotope Laboratories). The samples were centrifuged (10 min, 1,610 g, 4 μC), and the supernatants were injected directly onto a 150 mm 32.1 mm Atlantis HILIC column (Waters). The column was eluted isocratically with 5% mobile phase B (acetonitrile/0.1% formic acid) over 80 min. The ion spray voltage was 4.5 kV and the source temperature was 425 μC. All metabolites were measured using several reaction monitoring scans (MRM), MS settings, including declustering potentials and collision energies, for each metabolite were optimized by infusion of reference standards before sample analyses.

**Analysis Methods**

**Principal Component Analysis**

In the principal component analysis (PCA) of the metabolomics data, the data were first mean-centered. PCA was performed using the function “prcomp” from the “stats” package, part of the “R” language.

**Univariate Statistical Testing**

For the univariate statistical tests, no further scaling was performed. p-values were calculated using a two-sided paired t test, using the function “t.test,” part of the “R” language. p-values were corrected using the Benjamini-Hochberg false discovery rate procedure (as implemented in R). Pathway enrichment analysis: Pathway-Tools was used to perform the enrichment analysis of the dataset. The tool takes into account the biological pathway map (both metabolic and transcriptomic), but this tool does not provide a list of significantly differentially expressed metabolites/genes. Metabolites and genes were further analyzed using the KEGG pathway database.

**Animal Experiments**

C57BL/6J mice were trained by intraperitoneal injection with 1 mg β-glucan as previously described (Quintin et al., 2012). At 1 hr before and 2 hr after intraperitoneal injection of β-glucan or PBS, mice received an intraperitoneal injection of PBS, 200 μg BPTES, or 125 μg atorvastatin. After 7 days, mice were challenged with 10 g LPS intraperitoneally; after 3 hr, mice were sacrificed and circulating IL-1β and TNF concentrations were measured by ELISA (R&D Systems) according to the manufacturer’s instructions. The study was approved by the ethical animal committee of the University of Colorado, Denver.
were defined as significantly changed between two conditions if they had a FDR < 0.1. The second method used to perform pathway-enrichment analysis is “MetaboAnalyst!” (Xia et al., 2015), which does allow the definition of such a background set. MetaboAnalyst additionally has the advantage of performing a quantitative enrichment analysis instead of using a hard threshold, however, it does not allow the type of visualization that is provided by Pathway-tools. This complementary set of options was the reason for using both tools. A quantitative enrichment analysis was performed using the peak intensities as an input (before log2 transform). The settings were as follows: missing values were imputed as explained in Metabolomics Preprocessing and no data filtering or scaling was applied. The pathway-associated metabolite sets were used to check for enrichment (before and after log transformation), using all metabolites measured with mass spectrometry as a custom reference set. Pathways of less than four compounds were filtered from our analysis.

**Data Visualization**

The first explorative visualization was performed using Pathway-tools, which allows visualization of both transcriptomic and metabolomic data. Based on the pathways that were significantly differentially expressed in either the metabolomic or transcriptomic data, the interesting parts of the map were explored. Next, using the tool “Escher” (King et al., 2015), a pathway map was created, containing just the parts found to be of interest. A schematic overview of the pathways is depicted in Figure 1C (the complete map as was created, containing just the parts found to be of interest). A tool to explore metabolomic or transcriptomic data, the interesting parts of the map were exploited. Next, using the tool “Escher” (King et al., 2015), a pathway map was created, containing just the parts found to be of interest. A schematic overview of the pathways is depicted in Figure 1C (the complete map as created by Escher is depicted in Figure S1).
