A search for heavy resonances decaying to a $W$ or $Z$ boson and a Higgs boson in the $qq^{(*)}\bar{b}b$ final state is described. The search uses 36.1 fb$^{-1}$ of proton–proton collision data at $\sqrt{s} = 13$ TeV collected by the ATLAS detector at the CERN Large Hadron Collider in 2015 and 2016. The data are in agreement with the Standard Model expectations, with the largest excess found at a resonance mass of 3.0 TeV with a local (global) significance of 3.3 (2.1) $\sigma$. The results are presented in terms of constraints on a simplified model with a heavy vector triplet. Upper limits are set on the production cross-section times branching ratio for resonances decaying to a $W$ ($Z$) boson and a Higgs boson, itself decaying to $\bar{b}b$, in the mass range between 1.1 and 3.8 TeV at 95% confidence level; the limits range between 83 and 1.6 fb (77 and 1.1 fb) at 95% confidence level.

1. Introduction

The discovery of the Higgs boson [1,2] confirms the validity of the Standard Model (SM) in the description of particle interactions at energies up to a few hundred GeV. However, radiative corrections to the Higgs boson mass drive its value to the model's validity limit, indicating either extreme fine-tuning or the presence of new physics at an energy scale not far above the Higgs boson mass. It is natural to expect such new physics to manifest itself through significant coupling to the Higgs boson, for example in decays of new particles to a Higgs boson and other SM particles. This Letter presents a search for resonances produced in 36.1 fb$^{-1}$ of proton–proton ($pp$) collision data at $\sqrt{s} = 13$ TeV which decay to a $W$ or $Z$ boson and a Higgs boson. Such resonances are predicted in multiple models of physics beyond the SM, e.g. composite Higgs [3,4] or Little Higgs [5] models, or models with extra dimensions [6,7].

This search is conducted in the channel where the $W$ or $Z$ and Higgs bosons decay to quarks. The high mass region, with resonance masses $m_{VH} > 1$ TeV ($V = W, Z$), where the $V$ and $H$ bosons are highly Lorentz boosted, is considered. The $V$ and $H$ boson candidates are each reconstructed in a single jet, using jet substructure techniques and $b$-tagging to suppress the dominant background from multijet events and to enhance the sensitivity to the dominant $H \to bb$ decay mode. The reconstructed dijet mass distribution is used to search for a signal and, in its absence, to set bounds on the production cross-section times branching ratio for new bosons which decay to a $W$ or $Z$ boson and a Higgs boson.

The results are expressed as limits in a simplified model which incorporates a heavy vector triplet (HVT) [8,9] of bosons; this choice allows the results to be interpreted in a large class of models. The new heavy vector bosons couple to the Higgs boson and SM gauge bosons with coupling strength $c_{HgV}$ and to the SM fermions with coupling strength $(g^2/g_V) c_F$, where $g$ is the SM SU(2)$_L$ coupling constant. The parameter $g_V$ characterizes the interactions of the new vector bosons, while the dimensionless coefficients $c_{H}$ and $c_F$ parameterize departures of this typical strength for interactions with the Higgs and SM gauge bosons and with fermions, respectively, and are expected to be of order unity in most models. Two benchmark models are used: in the first, referred to as ModelA, the branching ratios of the new heavy vector boson to known fermions and gauge bosons are comparable, as in some extensions of the SM gauge group [10]. In ModelB, fermionic couplings to the new heavy vector boson are suppressed, as for example in a composite Higgs model [11]. The regions of HVT parameter space studied correspond to the production of resonances with an intrinsic width that is narrow relative to the experimental resolution. The latter is roughly 8% of the resonance mass. The sensitivity of the analysis to wider resonances is not tested. In addition, while the production rates of the new heavy charged and neutral states are related within the HVT model, the search pre-

sented here assumes the production of only a charged or neutral resonance and not both simultaneously.

Searches for $VH$ resonances, $V'$, have recently been performed by the ATLAS and CMS collaborations. The ATLAS searches (using leptonic $V$ decays) based on data collected at $\sqrt{s} = 8$ TeV set a lower limit at the 95% confidence level (CL) on the $W'$ ($Z'$) mass at 1.47 (1.36) TeV in HVT benchmark Model A with $g_V = 1$ [12]. Using the same decay modes, a search based on 3.2 fb$^{-1}$ of data collected at $\sqrt{s} = 13$ TeV set a 95% CL lower limit on the $W'$ ($Z'$) mass at 1.75 (1.49) TeV [13] in the HVT benchmark Model A. For Model B the corresponding limits are 2.22 (1.58) TeV. Searches by the CMS Collaboration at $\sqrt{s} = 8$ TeV in hadronic channels, based on HVT benchmark Model B with $g_V = 3$, exclude heavy resonance masses below 1.6 TeV ($W' \rightarrow WH$), below 1.1 TeV and between 1.3 TeV and 1.5 TeV ($Z' \rightarrow ZZ$), and below 1.7 TeV (combined $V' \rightarrow VH$) [14] at the 95% CL. Using the $W' \rightarrow WH \rightarrow ℓνbb$ channel, CMS excludes new heavy vector bosons with masses up to 1.5 TeV in the same context [15]. The CMS Collaboration also carried out a search for a narrow resonance decaying to $ZH$ in the $qq\ell^+\ell^-$ final state, setting limits on the $Z'$ production cross-section [16]. Searches for heavy resonances in HVT models have also been carried out in the hadronic $WW/WZ/ZZ$ channels by the ATLAS experiment at $\sqrt{s} = 13$ TeV with 3.2 fb$^{-1}$ of data [17]. For Model B, a new gauge boson with mass below 2.6 TeV is excluded at the 95% CL. The CMS Collaboration combined [18] diboson resonance searches at $\sqrt{s} = 8$ and 13 TeV [18], setting lower limits for $W'$ and $Z'$ singlets at 2.3 TeV and for a triplet at 2.4 TeV. As this Letter was being finalized, the CMS Collaboration released [19] a search in the same final state as studied in this Letter, using 36 fb$^{-1}$ of data collected at $\sqrt{s} = 13$ TeV. For Model B, a $W'$ boson with mass below 2.45 TeV and between 2.78 TeV and 3.15 TeV is excluded at the 95% CL. For a $Z'$ boson, masses below 1.19 TeV and between 1.21 TeV and 2.26 TeV are excluded at the 95% CL.

2. ATLAS detector

The ATLAS detector [20] is a general-purpose particle detector used to investigate a broad range of physics processes. It includes inner tracking devices surrounded by a 2.3 m diameter superconducting solenoid, electromagnetic and hadronic calorimeters and a muon spectrometer with a toroidal magnetic field. The inner detector consists of a high-granularity silicon pixel detector, including the insertable B-layer [21] installed after Run 1 of the LHC, a silicon strip detector, and a straw-tube tracker. It is immersed in a 2 T axial magnetic field and provides precision tracking of charged particles with pseudorapidity $|η| < 2.5$. The calorimeter system consists of finely segmented sampling calorimeters using lead/liquid-argon for the detection of electromagnetic (EM) showers up to $|η| < 3.2$, and copper or tungsten/liquid-argon for electromagnetic and hadronic showers for $1.5 < |η| < 4.9$. In the central region ($|η| < 1.7$), a steel/scintillator hadronic calorimeter is used. Outside the calorimeters, the muon system incorporates multiple layers of trigger and tracking chambers within a magnetic field produced by a system of superconducting toroids, enabling an independent precise measurement of muon track momenta for $|η| < 2.7$. A dedicated trigger system is used to select events [22]. The first-level trigger is implemented in hardware and uses the calorimeter and muon detectors to reduce the accepted rate to 100 kHz. This is followed by a software-based high-level trigger, which reduces the accepted event rate to 1 kHz on average.

3. Data and simulation samples

This analysis uses 36.1 fb$^{-1}$ of LHC pp collisions at $\sqrt{s} = 13$ TeV collected in 2015 and 2016. The data were collected during stable beam conditions with all relevant detector systems functional. Events were selected using a trigger that requires a single anti-$k_t$ jet [23] with radius parameter $R = 1.0$ (large-$R$ jet) with a transverse energy ($E_T$) threshold of 360 (420) GeV in 2015 (2016). The trigger requirement is $> 99\%$ efficient for events passing the offline selection of a large-$R$ jet with transverse momentum ($p_T$) $> 450$ GeV.

Signal processes, as well as backgrounds from $t\bar{t}$ and $W/Z +$ jets production, are modelled with Monte Carlo (MC) simulation. While multijet MC events are used as a cross-check, the primary multijet background estimation is performed using data as described in Section 6. The signal is modelled using benchmark Model A with $g_V = 1$. Results derived from this model can be directly applied to benchmark Model B by rescaling the relevant branching ratios. The signal was generated with Madgraph5_aMC@NLO 2.2.2 [24] interfaced to Pythia 8.186 [25] for parton shower and hadronization, with the NNPDF2.3 next-to-leading order (NLO) parton distribution function (PDF) set [26] and a set of tuned parameters called the ATLAS A14 tune [27] for the underlying event. The Higgs boson mass was set to 125.5 GeV, and Higgs boson decays to both $bb$ and $cc$, assuming SM branching ratios, were included in the simulation. The $V' \rightarrow VH \rightarrow q\bar{q}'(bb + cc)$ signal cross-section in Model B ranges from 110 fb (203 fb) for neutral (charged) resonances with a mass of 1 TeV, down to 0.09 fb (0.19 fb) for neutral (charged) resonances with a mass of 3.8 TeV. Samples were generated in steps of 100 GeV or 200 GeV up to 4 TeV.

The $t\bar{t}$ background samples were generated with Powheg-Box v2 [28] with the CT10 PDF set [29], interfaced with Pythia 6.428 [30] and the Perugia 2012 tune for the parton shower [31] using the CTEQ6L1 PDF set [32]. The cross-section of the $t\bar{t}$ process is normalized to the result of a quantum chromodynamics (QCD) calculation at next-to-next-to-leading order and log (NNLO+NLL), as implemented in Top++ 2.0 [33]. The Powheg-HDamp parameter [34] was set to the top quark mass, taken to be $m_t = 172.5$ GeV. The $W$-jets and $Z$-jets background samples were generated with Sherpa 2.1.1 [35] interfaced with the CT10 PDF set. Matrix elements of up to four extra partons were calculated at leading order in QCD. Only the hadronic decays of the $W$ and $Z$ bosons were included. For studies with simulated multijet events, the MC samples were generated with Pythia 8.186 [25], with the NNPDF2.3 NLO PDF and the ATLAS A14 tune. The background from SM diboson and $V +$ jets production is negligible and therefore not considered.

For all simulated events, except those produced using Sherpa, EvtGen v1.2.0 [36] was used to model the properties of bottom and charm hadron decays. The detector response was simulated with GEANT 4 [37,38] and the events were processed with the same reconstruction software as that used for data. All simulated samples include the effects due to multiple $pp$ interactions per bunch-crossing (pile-up).

4. Event reconstruction

Collision vertices are reconstructed requiring a minimum of two tracks each with transverse momentum $p_T > 0.4$ GeV. The primary
vertex is chosen to be the vertex with the largest \( \sum p_T^2 \), where the sum extends over all tracks associated with the vertex.

The identification and reconstruction of hadronically decaying gauge boson and Higgs boson candidates is performed with the anti-\( k_t \) jet clustering algorithm with \( R \) parameter equal to 1.0. These large-\( R \) jets [39] are reconstructed from locally calibrated topological clusters [40] of calorimeter energy deposits. To mitigate the effects of pile-up and soft radiation, the large-\( R \) jets are trimmed [41]: the jet constituents are reclustered into subjets using the \( k_t \) algorithm [42] with \( R = 0.2 \), removing those with \( p_T^{\text{jet}} / p_T^{\subjet} < 0.05 \), where \( p_T^{\subjet} \) is the transverse momentum of the subjet and \( p_T^{\text{jet}} \) is the transverse momentum of the original large-\( R \) jet. In order to improve on the limited angular resolution of the calorimeter, the combined mass of a large-\( R \) jet is computed using a combination of calorimeter and tracking information [43]. The combined mass is defined as:

\[
M_j \equiv M_{\text{wa}} \times M_j^{\text{calo}} + W_{\text{track}} \times \left( M_j^{\text{track}} \frac{p_T^{\text{calo}}}{p_T^{\text{jet}}} \right)
\]

where \( M_j^{\text{calo}} \) is the calorimeter-only estimate of the jet mass (\( p_T \)), and \( M_j^{\text{track}} \) is the jet mass estimated via tracks with \( p_T > 0.4 \) GeV associated with the large-\( R \) jet using ghost association [44]. To correct for the missing neutral component in the track-based measurement, \( M_j^{\text{track}} \) is scaled by the ratio of calorimeter to track \( p_T \) estimates. The weighting factors \( W_{\text{wa}} \) and \( W_{\text{track}} \) are \( p_T^{\text{calo}} \)-dependent functions of the calorimeter- and track-based jet mass resolutions used to optimize the combined mass resolution.

Track jets clustered using the anti-\( k_t \) algorithm with \( R = 0.2 \) are used to aid the identification of \( b \)-hadron candidates from the Higgs boson decay [45]. Track jets are built from charged particle tracks with \( p_T > 0.4 \) GeV and \( |\eta| < 2.5 \) that satisfy a set of hit and impact parameter criteria to minimize the impact of tracks from pile-up interactions, and are required to have track jet \( p_T > 10 \) GeV, \( |\eta| < 2.5 \), and at least two tracks clustered in the track jet. Track jets are matched with large-\( R \) jets using ghost association. The identification of \( b \)-hadrons relies on a multivariate tagging algorithm [46] which combines information from several vertexing and impact parameter tagging algorithms applied to a set of tracks in a region of interest around each track jet axis. The \( b \)-tagging requirements result in an efficiency of 77% for track jets containing \( b \)-hadrons, and a misidentification rate of \( \sim 2\% \) \((\sim 24\%\) for light-flavour \((\text{charm})\) jets, as determined in a sample of simulated \( \ell \ell \) events. For MC samples the tagging efficiencies are corrected to match those measured in data [47].

Muons are reconstructed by combining tracks in the inner detector and the muon system, and are required to satisfy “Tight” muon identification criteria [48]. The four-momentum of the closest muon candidate with \( p_T > 4 \) GeV and \( |\eta| < 2.5 \) that is within \( \Delta R = \sqrt{(\Delta \eta)^2 + (\Delta \phi)^2} = 0.2 \) of a track jet is added to the calorimeter jet four-momentum to partially account for the energy carried by muons from semileptonic \( b \)-hadron decays. This muon correction results in a \( \sim 5\% \) resolution improvement for Higgs boson candidate jets (defined in Section 5) [49]. Electrons are reconstructed from inner detector and calorimeter information, and are required to satisfy the “Loose” likelihood selection [50].

Leptons \((\text{electrons and muons, } \ell)\) are also used in a “veto” to ensure the orthogonality of the analysis selection with respect to other heavy \( VH \) resonance searches in non-fullly hadronic final states. The considered leptons have \( p_T > 7 \) GeV, \( |\eta| < 2.5 \) \((2.47)\) for muons \((\text{electrons})\), and their associated tracks must have \( |d_0|/\sigma_0 < 3 \) \((5)\) and \( z_0 \sin \theta < 0.5 \) mm, where \( d_0 \) is the transverse impact parameter with respect to the beam line, \( \sigma_0 \) is the uncertainty on \( d_0 \), and \( z_0 \) is the distance between the longitudinal position of the track along the beam line at the point where \( d_0 \) is measured and the longitudinal position of the primary vertex. Leptons are also required to satisfy an isolation criterion, whereby the ratio of the \( p_T \) sum of all tracks with \( p_T > 1 \) GeV \((\text{excluding the lepton})\) within a cone around the lepton \((\text{with radius dependent on the lepton } p_T)\) to the lepton momentum must be less than a \( p_T \)- and \( |\eta| \)-dependent threshold \( I_0 \). The value of \( I_0 \) is chosen such that a constant efficiency of 95% is achieved as a function of \( p_T \) and \( |\eta| \) is obtained for leptons in events identified with \( Z \rightarrow \ell \ell \) candidates.

The missing transverse momentum \( E_{\text{miss}} \) is calculated as the negative vectorial sum of the transverse momenta of all the muons, electrons, calorimeter jets with \( R = 0.4 \), and any inner-detector tracks from the primary vertex not matched to any of these objects [51]. The magnitude of the \( E_{\text{miss}} \) is denoted by \( E_{\text{miss}} \).
\( \beta = 1 \) which depends on whether the candidate is a W or a Z boson, as described in Ref. [52]. The variable \( D_2 \) exploits two- and three-point energy correlation functions to tag boosted objects with two-body decay structures. The \( V \)-jet tagging efficiency is \( \sim 50\% \) and constant in \( V \)-jet \( p_T \), with a misidentification rate for jets from multijet production of \( \sim 2\% \).

Four signal regions (SRs) are used in this analysis. They differ by the number of \( b \)-tagged track jets associated to the \( H \)-jet and by whether the \( V \)-jet passes a \( Z \)-tag or \( V \)-tag selection. The “1-tag” and “2-tag” SRs require exactly one and two \( b \)-tagged track jets associated to the \( H \)-jet, respectively. The 2-tag signal regions provide better sensitivity for resonances with masses below \( \sim 2.5 \) TeV. Above 2.5 TeV the 1-tag regions provide higher sensitivity because the Lorentz boost of the Higgs boson is large enough to merge the fragmentation products of both \( b \)-quarks into a single track jet. Events in which the \( V \)-jet passes a \( Z \)-tag constitute the \( ZH \) signal regions, while events in which the \( V \)-jet passes a \( W \)-tag constitute the \( WH \) signal regions. While the 1-tag and 2-tag signal regions are orthogonal regardless of the \( V \)-jet tag, the \( WH \) and \( ZH \) selections are not orthogonal within a given \( b \)-tag category. The overlap between the \( WH \) and \( ZH \) selections in the signal regions is approximately 60%.

The final event requirement is that the mass of the candidate resonance built from the sum of the \( V \)-jet and \( H \)-jet candidate four-momenta, \( m_{\ell j} \), must be larger than 1 TeV. This requirement ensures full efficiency for the trigger and jet \( p_T \) requirements for events passing the full selection. The full event selection can be found in Table 1. The expected selection efficiency for both \( WH \) and \( ZH \) resonances decaying to \( q\ell\bar{q}'(bb + cc) \) with a mass of 2 (3) TeV in the HVT benchmark Model \( B \) is \( \sim 30\% \) (\( \sim 20\% \)).

6. Background estimation

After the selection of 1-tag and 2-tag events, \( \sim 90\% \) of the background in the signal regions originates from multijet events. The remaining \( \sim 10\% \) is predominantly \( \ell\ell \) with a small contribution from \( V + \text{jets} \) (\( \lesssim 1\% \)). The multijet background is modelled directly from data, while other backgrounds are estimated from MC simulation.

Multijet modelling starts from the same trigger and event selection as described above, but the \( H \)-jet is required to have zero associated \( b \)-tagged track jets. This 0-tag sample, which consists of multijet events at the \( \sim 95\% \) level, is used to model the kinematics of the multijet background in the 1-tag and 2-tag SRs. To keep the 0-tag region kinematics close to the 1- and 2-tag regions, \( H \)-jets in 0-tag events must contain at least one (two) associated track jets when modelling the 1(2)-tag signal region.

The 0-tag sample is normalized to the 1-tag and 2-tag samples and corrected for kinematic differences with respect to the signal regions, as described below. These kinematic differences arise from the \( b \)-tagging efficiency variations as a function of \( p_T \) and \( |\eta| \) and because different multijet processes, in terms of quark, gluon, and heavy-flavour content, contribute different fractions to the 0-, 1-, and 2-tag samples.

The 0-tag sample is normalized to the 1- and 2-tag samples, separately, using a signal-free high mass sideband of the \( H \)-jet defined by 145 GeV < \( m_{\ell j} \) < 200 GeV. This sideband (SB), illustrated in Fig. 1, is orthogonal to the signal region and has similar expected event yield to the signal region. The normalization of the multijet events is set by scaling the number of events in each region of the 0-tag sample by

\[
\mu_{\text{Multijet}} = \frac{N_{1(2)-\text{tag Multijet}}}{N_{0-\text{tag Multijet}}} \frac{N_{1(2)-\text{tag data}}}{N_{0-\text{tag data}}} \frac{N_{1(2)-\text{tag data}} - N_{1(2)-\text{tag data}}}{N_{1(2)-\text{tag data}} - N_{V + \text{jets}} - N_{0-\text{tag Multijet}} - N_{0-\text{tag Multijet}} - N_{1(2)-\text{tag data}}},
\]

where \( N_{0(1/2)-\text{tag data}} \) and \( N_{1(2)-\text{tag data}} \) are the numbers of events observed in data, and predicted from \( \ell\ell \) and \( V + \text{jets} \) MC simulation in the 0-, 1-, or 2-tag SB samples, respectively. As the selection of track jets for \( H \)-jets in 0-tag events differs when modelling the 1-tag and 2-tag regions (as stated above), \( N_{0-\text{tag Multijet}} \) differs between estimates of the \( \mu_{\text{Multijet}} \).
The number of events in data and predicted background events in the sideband and validation regions. In the sideband, the data and the total background prediction agree by construction. The uncertainties are statistical only. Due to rounding the totals can differ from the sums of components.

![Fig. 2](attachment:image.png)

Fig. 2. The $m_{JJ}$ distribution in the signal-region-like validation region in the (left) 2-tag (right) 1-tag samples, compared to the predicted background. The uncertainty band corresponds to the statistical uncertainty on the multijet model.

is recomputed to ensure that the normalization is kept fixed. No explicit uncertainties are associated with this reweighting as these are determined from comparison with validation regions, as described below.

Due to the small number of events in the background template in the high $m_{JJ}$ tail, the backgrounds are modelled by fitting between 1.2 and 4 TeV with power-law and exponential functions. The multijet background in $m_{JJ}$ is modelled using the functional form

$$f_{\text{Multijet}}(x) = p_0(1 - x)^{p_1}(1 + x)^{p_2},$$

while the merged $t\bar{t}$ and V+jets backgrounds are modelled using the functional forms

$$f_{\text{Other}}^{1-tag}(x) = p_d(1 - x)^{p_1}x^{p_2},$$

and

$$f_{\text{Other}}^{2-tag}(x) = pg e^{-px^2}$$

for the 1-tag and 2-tag samples respectively. In these functional forms, $x = m_{JJ}/\sqrt{s}$, and $p_d$ through $p_4$ are parameters determined by the fit. These functional forms are used as they can model changes in the power-law behaviour of the respective backgrounds between high and low masses. The exponential function is used for the 2-tag $t\bar{t}$ and V+jets samples because it was found to model the tail of the distribution well and because a fit to the small statistics of the sample could not constrain a function with more parameters. Fits are performed separately for the 1-tag and 2-tag background estimates, and separately for each background.

The background model is validated in the two regions denoted by VR-SR and VR-SB in Fig. 1, each also with two subregions. In all of these, the V-jet is required to have mass 50 GeV < $m_{JJ} < 70$ GeV but the $D_2$ selection is only applied in one of the subregions. For the signal-region-like validation regions (VR-SR) the $H$-jet selection is unchanged, and for the sideband-like validation regions (VR-SB) the $H$-jet is required to have mass 145 GeV < $m_{JJ} < 200$ GeV. Both validation regions are kinematically similar to the signal regions but orthogonal to them (and to each other).

Table 2 compares the observed data yields in the validation regions with the corresponding background estimates. The differences are used as estimators of the background normalization uncertainties, as described in Section 7. The modelling of the $m_{JJ}$ distribution in the signal-region-like validation region is shown in Fig. 2 for the 1-tag and 2-tag samples. The data are well described...
by the background model. Other kinematic variables are generally well described.

7. Systematic uncertainties

The preliminary uncertainty on the combined 2015 and 2016 integrated luminosity is 3.2%. It is derived, following a methodology similar to that detailed in Ref. [55], from a preliminary calibration of the luminosity scale using $x$-$y$ beam-separation scans performed in 2015 and 2016.

Experimental systematic uncertainties affect the signal as well as the $t\bar{t}$ and $V+jets$ backgrounds estimated from MC simulation. The systematic uncertainties related to the scales of the large-$R$ jet $p_T$, mass and $D_2$ are of the order of 2%, 5% and 3%, respectively. They are derived following the technique described in Ref. [39]. The impacts of the uncertainties on the resolutions of each of these large-$R$ jet observables are evaluated by smearing the jet observable according to the systematic uncertainties of the resolution measurement [39,52]. A 2% absolute uncertainty is assigned to the large-$R$ jet $p_T$, mass and $D_2$ resolutions related 20% and 15% uncertainties are assigned, respectively. The uncertainty in the $b$-tagging efficiency for track jets is based on the uncertainty in the measured tagging efficiency for $b$-jets in data following the methodology used in Ref. [47]. This is measured as a function of $b$-jet $p_T$ and ranges between 2% and 8% for track jets with $p_T < 250$ GeV. For track jets with $p_T > 250$ GeV the uncertainty in the tagging efficiencies is extrapolated using MC simulation [47] and is approximately 9% for track jets with $p_T > 400$ GeV. A 30% normalization uncertainty is applied to the $t\bar{t}$ background based on the ATLAS $t\bar{t}$ differential cross-section measurement [56]. Due to the small contribution of the $V+jets$ background, no corresponding uncertainty is considered.

Systematic uncertainties in the normalization and shape of the data-based multijet background model are assessed from the validation regions. The background normalization predictions in the validation regions agree with the observed data to within $\pm 5\%$ in the 1-tag sample and $\pm 13\%$ in the 2-tag sample. These differences are taken as the uncertainties in the predicted multijet yield. The shape uncertainty is derived by taking the ratio of the predicted background to the observed data after fitting both to a power law. This is done separately for the 1-tag and 2-tag samples. The larger of the observed shape differences in the VR-SR and VR-SB is taken as the shape uncertainty. Separate shape uncertainties are estimated for $m_{jj}$ above and below 2 TeV in order to allow for independent shape variations in the bulk and tail of the $m_{jj}$ distribution in the final statistical analysis.

An additional uncertainty in the shape of the multijet background prediction is assigned by fitting a variety of empirical functions designed to model power-law behaviour to the 0-tag $m_{jj}$ distribution, as described in Ref. [57]. The largest difference between the nominal and alternative fit functions is taken as a systematic uncertainty. Similarly, the fit range of the nominal power-law function is varied, and the largest difference between the nominal and alternative fit ranges is taken as a systematic uncertainty.

The impact of the main systematic uncertainties on event yields is summarized in Table 3.

8. Results

The results are interpreted using the statistical procedure described in Ref. [1] and references therein. A test statistic based on the profile likelihood ratio [58] is used to test hypothesized values of $\mu$, the global signal strength factor, separately for each model considered. The statistical analysis described below is performed using the $m_{jj}$ distribution of the data observed in the signal regions. The systematic uncertainties are modelled with Gaussian or log-normal constraint terms (nuisance parameters) in the definition of the likelihood function. The data distributions from the 1-tag and 2-tag signal regions are used in the fit simultaneously, treating systematic uncertainties on the luminosity, jet energy scale, jet energy resolution, jet mass resolution and $b$-tagging as fully correlated between the two signal regions. Both the multijet normalization and shape uncertainties are treated as independent between the two signal regions. In addition, the multijet shape uncertainties for $m_{jj}$ above and below 2 TeV are treated as independent. When performing the fit, the nuisance parameters are allowed to vary within their constraints to maximize the likelihood. As a result of the fit, the multijet shape uncertainties are significantly reduced. With the jet mass resolution, jet energy scale and multijet normalization, they have the largest impact on the search sensitivity. Fits in the $W+H$ and $Z+H$ signal regions are performed separately. The pre- and post-fit $m_{jj}$ distributions in the signal regions are shown in Fig. 3.

The number of background events in the 1-tag and 2-tag $Z+H$ and $W+H$ signal regions after the fit, the number of events ob-

Fig. 3. The $m_{JJ}$ distributions in the $VH$ signal regions for data (points) and background estimate (histograms) after the likelihood fit for events in the (left) 2-tag and (right) 1-tag categories. The pre-fit background expectation is given by the blue dashed line. The expected signal distributions (multiplied by 50) for a HVT benchmark Model B $V'$ boson with 2 TeV mass are also shown. In the data/prediction ratio plots, arrows indicate off-scale points.

Table 4

The number of predicted background events in the $VH$ 1-tag and 2-tag signal regions after the fit, compared to the data. The "Other backgrounds" entries include both $t\bar{t}$ and $V\gamma$ jets. Uncertainties correspond to the total uncertainties in the predicted event yields, and are smaller for the total than for the individual contributions because the latter are anti-correlated. The yields for $m = 2$ TeV $V'$ bosons decaying to $VH$ in Model B are also given. Due to rounding the totals can differ from the sums of components.

served in the data, and the predicted yield for a potential signal are reported in Table 4. The total data and background yields in each region are constrained to agree by the fit. There is a ~ 60% overlap of data between the $WH$ and $ZH$ selections for both the 2-tag and 1-tag signal regions, and this fraction is approximately constant as a function of $m_{JJ}$. This overlap is similar when examining the signal MC simulation, for instance for the 2 TeV $Z'$ signal MC approximately ~ 60% of events pass both the $WH$ and $ZH$ selections.

8.1. Statistical analysis

To determine if there are any statistically significant local excesses in the data, a test of the background-only hypothesis ($\mu = 0$) is performed at each signal mass point. The significance of an excess is quantified using the local $p_0$ value, the probability that the background could produce a fluctuation greater than or equal to the excess observed in data. A global $p_0$ is also calculated for the most significant discrepancy, using background-only pseudo-experiments to derive a correction for the look-elsewhere effect across the mass range tested [59]. The most significant deviation from the background-only hypothesis is in the $ZH$ signal region, occurring at $m_{JJ} \approx 3.0$ TeV with a local significance of 3.3 $\sigma$. The global significance of this excess is 2.1 $\sigma$, which is computed considering the full range of $Z'$ masses examined for potential signals from 1.1 TeV to 3.8 TeV.

The data are used to set upper limits on the cross-sections for the different benchmark signal processes. Exclusion limits are computed using the CL$_{s}$ method [60], with a value of $\mu$ regarded as excluded at the 95% CL when CL$_{s}$ is less than 5%.

Fig. 4 shows the 95% CL cross-section upper limits on HVT resonances for both Model A and Model B in the $WH$ and $ZH$ signal regions for masses between 1.1 and 3.8 TeV. Limits on $\sigma(pp \rightarrow V' \rightarrow VH) \times B(H \rightarrow \bbbar + c\bar{c})^3$ are set in the range of

---

1 The signal samples contain Higgs boson decays to $\bbbar$ and $c\bar{c}$, but due to the branching ratios and $b$-tagging requirements the sensitivity is dominated by $H \rightarrow \bbbar$. 

---

83 fb to 1.6 fb and 77 fb to 1.1 fb in the W and ZH signal regions, respectively. These cross-section limits are translated into excluded ModelB signal mass ranges of 1.10–2.50 TeV for W H resonances and 1.10–2.60 TeV for ZH resonances. The corresponding excluded mass ranges for ModelA are 1.10–2.40 TeV for W H resonances, and 1.10–1.48 TeV and 1.70–2.35 TeV for ZH resonances.

Fig. 5 shows the 95% CL limits in the $g^2 c_F / g_V$ vs. $g_V c_H$ plane for several resonance masses for both the W and ZH channels. These limits are derived by rescaling the signal cross-sections to the values predicted for each point in the $(g^2 c_F / g_V, g_V c_H)$ plane and comparing with the observed cross-section upper limit. As the resonance width is not altered in this rescaling, areas for which the resonance width $\Gamma / m > 5\%$ are shown in grey. These may not be well described by the narrow width approximation assumed in the rescaling.

9. Summary

A search for resonances decaying to a W or Z boson and a Higgs boson has been carried out in the $pp \rightarrow t\bar{t}bb$ channel with 36.1 fb$^{-1}$ of pp collision data collected by ATLAS during the 2015 and 2016 runs of the LHC at $\sqrt{s} = 13$ TeV. Both the vector boson and Higgs boson candidates are reconstructed using large-radius jets, and jet mass and substructure observables are used to tag W, Z and Higgs boson candidates and suppress the dominant multijet background. In addition, small-radius $b$-tagged track jets ghost-associated to the large-$R$ jets are exploited to select the Higgs boson candidate jet. The data are in agreement with the Standard Model expectations, with the largest excess observed at $m_{1j} \simeq 3.0$ TeV in the ZH channel with a local significance of 3.3 $\sigma$. The global significance of this excess is 2.1 $\sigma$. Upper limits on the production cross-section times the Higgs boson branching ratio to the $bb$ final state are set for resonance masses in the range between 1.1 and 3.8 TeV with values ranging from 83 fb to 1.6 fb and 77 fb to 1.1 fb (at 95% CL) for W H and ZH resonances, respectively. The corresponding excluded heavy vector triplet ModelB signal mass ranges are 1.1–2.5 TeV for W H resonances, and 1.1–2.6 TeV for ZH resonances.

Acknowledgements

We thank CERN for the very successful operation of the LHC, as well as the support staff from our institutions without whom ATLAS could not be operated efficiently.
