Interleukin-6 in relation to other proinflammatory cytokines, chemotactic activity and neutrophil activation in rheumatoid synovial fluid

Miek A van Leeuwen, Johanna Westra, Pieter C Limburg, Piet L C M van Riel, Martin H van Rijswijk

Abstract

Objective—To evaluate the relation between synovial fluid (SF) concentrations of interleukin-6 (IL-6) and other mediators of inflammation which are responsible for joint degradation in rheumatoid arthritis (RA).

Methods—We measured IL-6, IL-1β, tumour necrosis factor α (TNFα), granulocyte macrophage colony stimulating factor, IL-8, and polymorphonuclear leucocyte (PMNL) chemotaxis and degranulation in SF from patients with RA (n = 30) in the early phase of the disease.

Results—In a cross-sectional study IL-6 concentrations correlated with those of IL-1β, IL-8 and with PMNL activation as reflected by lactoferrin concentrations. In a longitudinal study, changes in IL-6 concentrations correlated with changes in TNFα, IL-8 and lactoferrin concentrations.

Conclusion—IL-6 in SF appears to reflect the local proinflammatory, potentially erosive activity in RA. This supports the use of acute phase proteins, which are mainly induced by IL-6, as variables to monitor the course of RA.

(Rheum Dis 1995; 54: 33–38)

Rheumatoid arthritis (RA) is a systemic inflammatory disease localised preferentially in the synovial joints. Chronic synovitis often leads to irreversible destruction of cartilage and periarticular bone. The inflamed synovium is characterised by infiltration of macrophages, T and B cells, and local proliferation of synoviocytes. The highly active macrophages and synoviocytes have been shown to be strong producers of cytokines, in particular the proinflammatory cytokines such as interleukin-1 (IL-1), tumour necrosis factor α (TNFα), interleukin-8 (IL-8), granulocyte macrophage colony stimulating factor (GM-CSF) and interleukin-6 (IL-6).1 2

Proinflammatory cytokines are thought to play a major role in chronic inflammation and joint destruction in RA. IL-1 and TNFα stimulate the proliferation of synoviocytes and the secretion of prostaglandins, collagenase, stromelysin, neutrophil proteases, and oxygen radicals, thus having potent catabolic actions on cartilage and bone.1 Both also induce the synthesis and secretion of other cytokines in the synovium, in particular IL-6 and IL-8.1 2 4 5

The activities of IL-8 include chemotactic attraction and activation of polymorphonuclear leucocytes (PMNL),4 6 These PMNL, which may be present in large numbers in the synovial fluid, are thought to contribute to destruction of cartilage through the release of degradative enzymes.7

The local tissue damaging potential of IL-6 is not clear; it does not, for example, stimulate the production of prostaglandin E2 or proteinases by human synovial cells, and has no catabolic properties. However, IL-6 is the major inducer of the systemic acute phase response, in particular of hepatic acute phase proteins.8 The acute phase response, as measured by the erythrocyte sedimentation rate (ESR) or C reactive protein (CRP) concentrations, is commonly used in clinical practice to monitor disease activity. In previous studies a correlation between the course of clinical disease activity (as measured by joint swelling), serum concentrations of CRP, and progression of radiological joint damage has been demonstrated.9 10 Moreover, IL-6 concentrations in synovial fluid have been shown to be related to local disease activity in rheumatoid arthritis.12

The aim of the present study was to evaluate to what extent concentrations of IL-6 in the synovial fluids of patients with early RA may be considered to be representative of those of the group of factors which are thought to play a major role in joint destruction.

Patients and methods

Patients

One hundred consecutive patients attending the Department of Rheumatology, Groningen, who had rheumatoid arthritis (American Rheumatism Association (ARA) criteria) of disease duration less than one year, were invited to participate in a prospective follow up study. Disease onset was defined as the date on which the patient first presented complaining of the disease. Synovial fluid (SF) was obtained from 30 of these patients in an early phase of the disease during therapeutic arthrocentesis of actively inflamed painful swollen joints. In all cases corticosteroid (triamcinolone) was administered into the joint after aspiration of the SF. Fourteen patients had more than one aspiration early in the course of the disease,
and 61 different samples (knee 54, shoulder 7) were available for analysis. Mean duration of the disease until the first aspiration was 21 months (range 3-50, median 17) and the mean time between two aspirations was seven months (range 1-25, median 7). All patients but one were rheumatoid factor positive. At the time of the aspiration, all patients were treated with non-steroidal anti-inflammatory drugs (NSAIDs) and 23 received disease modifying anti-rheumatic drugs (DMARDs) in addition (hydralazine n = 10, i.e. gold n = 9, d-penicillamine n = 4). Four patients were treated with low dose prednisolone.

SF samples were collected into sterile tubes with EDTA and immediately placed on melting ice. Cells were removed by centrifugation and SF were stored at -20°C until use. Before assay each SF was treated with hyaluronidase (Sigma, type I-S, St Louis, MO) at a concentration of 10 U/ml for one hour at 37°C and then centrifuged at high speed to remove particles. Hyaluronidase treatment was performed to decrease the viscosity of the SF and to prevent the possible interference in the immunoassays of the combined presence of rheumatoid factor and hyaluronic acid.

**CYTOKINE ASSAYS**

IL-6 was determined by bioassay with the IL-6-dependent mouse hybridoma cell line B9.14 Heat inactivated synovial fluid samples were serially diluted in medium consisting of RPMI-1640 (Gibco BRL, Gaithersburg, MD) supplemented with 13% fetal calf serum, 60 µg/ml gentamycin, 2 mmol/l glutamin, 1 mmol/l sodium pyruvate and 50 µmol/l β-mercaptoethanol; 60 µl test samples were added to 96 well culture plates (Costar, Cambridge, MA). Five thousand cells per well were added to a final volume of 100 µl and cultured for 72 hours. Cell proliferation was measured in a colorimetric assay with MTT-tetrazolium (Sigma) as described by Mosman.15 As standard we used recombinant human IL-6 (107 U/mg) from Genzyme (Boston, MA).

In addition, concentrations of IL-6 were determined with two different immunoassays. The first was an ELISA as described by Helle et al10 using a combination of the monoclonal antibody, mAb IL-6-16, and the polyclonal antibody, Sh-a-IL-6. The sheep anti-IL-6 was biotinylated using LC-biotin-N-hydroxysuccinimide ester (Pierce, Rockford, IL) according to the manufacturer's instructions. SF were measured in four serial dilutions (40-160-640-2560×) in the presence of an excess of normal sheep serum and after incubation the microplates were washed with phosphate buffered saline with 0.05% Tween-20 before incubation with streptavidine-horse-radish peroxidase (HRPO) (Dakopatts A/S, Denmark) at 100-fold dilution. Signal amplification was then performed by catalysed reporter deposition using 15 minutes of incubation with biotin-tyramine (BT) prepared as described by Bobrow according to method A.17 A second incubation with streptavidine-HRPO (1000× dilution) for 15 minutes was performed. Ortho-phenylenediamine was added and after 20 minutes the reaction was terminated with 1 mol/l H2SO4. The absorbance was read at 492 nm on a Titertek Multiscan. As standard we used recombinant human IL-6 (Genzyme) with a detection range of 0.8-100 pg/ml.

The second immunoassay for IL-6 in SF was an IL-6 enzyme amplified sensitivity immunoassay (EASIA) (kit by Medgenix Diagnostics, Fleurus Belgium). Monoclonal antibodies directed against distinct epitopes of IL-6 were used; samples were diluted 50-fold, standards were in the range 20-2000 pg/ml. The colour reaction was performed with tetramethyl-benzidine and hydrogen peroxide and absorbance was read at 450 nm and 490 nm on a Vmax EASIA reader. Data were calculated using a polychromatic data reduction method (kindly provided by Medgenix).

For measurement of IL-1β, TNFα and GM-CSF in SF we used EASIA's (Medgenix) in which samples were tested undiluted, monoclonal antibodies were used and reading was according to the method used in the IL-6 EASIA. IL-1β and GM-CSF standards were in the range 25-2000 pg/ml, TNFα standards in the range 15-1500 pg/ml. Soluble TNF receptors do not interfere with the detection of TNFα in this EASIA, in which the same reagents are used as in the TNF-immunoradiometric assay (Medgenix).18

IL-1β in SF was also tested in a high sensitivity IL-1β ELISA kit (Cistron Biotechnology, Pinebrook, NJ). A monoclonal antibody was used as coating antibody and a polyclonal rabbit anti-IL-1β as detecting antibody. Samples were diluted fivefold and standards were in the range 5-150 pg/ml; the lower limit of detection was 5 pg/ml.

IL-8 in SF was determined using a human IL-8 immunoassay (Quantikine, R & D Systems, Abingdon, UK). A monoclonal antibody to IL-8 was coated to the microtitreplate; the second antibody consisted of an HRP-labelled polyclonal antibody. The standard consisted of recombinant human IL-8 used in concentrations of 25-3000 pg/ml; samples were diluted 10-fold.

**CHEMOTAXIS ASSAY**

Normal human PMNL were isolated from freshly drawn venous blood anticoagulated with EDTA, from the same donor for each assay. After density gradient centrifugation on Lymphoprep (Nycomed Pharma AS, Oslo, Norway) neutrophils were separated from erythrocytes by lysis for 10 minutes with cold ammonium chloride (155 mmol/l NH4Cl, 0-1 mmol/l EDTA). Cells were washed twice with 0.9% saline, once with Hank's balanced salt solution (HBSS) (Gibco) and suspended in HBSS with 0-5% bovine serum albumin (HBSA) at 2-5 106 cells/ml. Cell viability was tested by Trypan Blue exclusion and was >97%.

Chemotaxis was measured according to Boyden,19 using blind well chambers (Neuro-
IL-6: relation to cytokines, chemotaxis and neutrophils in rheumatoid synovial fluid

Results

IL-6 concentrations in all 61 SF samples were measured with three assays. Hyaluronidase treatment had no influence on results of IL-6 measurements. Possible interference by IgM-RF was unlikely because samples were measured in the presence of an excess of normal sheep serum; furthermore, there was no correlation between the SF concentrations of IL-6 and those of IgM-RF (present in concentrations of 5–850 (mean 153, median 65) IU/ml (data not shown)). The Pearson correlation coefficient between bioassay results and the EASIA was 0.915, between bioassay and the IL-6 ELISA was 0.809, and between EASIA and ELISA was 0.890 (all highly significant: n = 61, p < 0.001). For further calculations we used the IL-6 values of the bioassay and the ELISA.

Table 1 shows the results of the cytokine measurements in the first SF sample of each patient (n = 30), including IL-6. Concentrations of IL-1β and GM-CSF were below the detection limit in all EASIA samples, but IL-1β was detectable in all ELISA samples. Positive results for TNFα and IL-8 were obtained in all samples. There was no influence of hyaluronidase treatment on the results of these IL-1β, TNFα and IL-8 measurements.

CHEMOTAXIS ASSAY

This assay appeared to be sensitive, as 10 ng/ml IL-8 gave a mean CTI of 51.8 (SD 5.8)% in six different experiments with PMNL from the same donor. Mean CTI in the SF samples, tested in a dilution of 1:20, was 32.5% (2–62%, median 30%). In this 1:20 dilution, all SF samples yielded results within the linear range of the assay. Addition of TNFα or IL-1, or both, to a range of concentrations of IL-8 corresponding to those found in SF samples, did not increase the chemotactic response in this assay compared with IL-8 alone (data not shown). Chemotaxis induced by an excess of recombinant human IL-8 (50–200 ng/ml), leading to a plateau of chemotaxis (CTI 60%), was totally inhibited by addition of 4 ng/ml anti-IL-8; that of SF (measured at 1:20 dilution) was inhibited by 22 (28)% (range <5–77%) in eight SF samples in either the presence or the absence of 4 μg/ml anti-IL-8.

INTERRELATION BETWEEN IL-6 AND OTHER CYTOKINES, LACTOFERRIN AND CHEMOTAXIS IN SF

Table 2 shows the Spearman correlation matrix for the results of IL-6, IL-1β, TNFα, IL-8, lactoferrin, and chemotactic index, as measured in the first sample of each patient (n = 30). IL-6 correlated significantly with IL-1β (p < 0.01) and IL-8 (p < 0.02), but not with TNFα (p > 0.1). In addition, a significant correlation (p < 0.001) was found between concentrations of IL-6 and those of lactoferrin.
(present in concentrations of 1.3–67 (mean 14.3; median 9) μg/ml). A similar significance was found for the correlation between IL-6 and lactoferrin concentrations, but correlations between C/T and individual cytokines or lactoferrin were not significant. Adding in the different cytokines as variables in a multiple regression analysis, no improvement in the prediction of the CTI was observed.

In 12 patients more than one aspiration of the same knee was necessary because of a flare of the arthritis in that joint. Patients with recurrent joint effusions appeared to have significantly greater concentrations of IL-6, IL-8, and lactoferrin (first SF sample from each patient) than patients with incidental knee swelling. The differences between the two groups could not be related to differences in treatment with DMARDs or prednisolone, which was similar for both groups.

In patients with recurrent swelling of the same joint, we analysed whether changes in IL-6 concentrations in the successive SF samples were related to changes in concentrations of other cytokines and lactoferrin by expressing the cytokine and lactoferrin values in the second and occasional third aspirate as percentages of the values in the first SF for each patient. In the sequential samples both higher and lower values were found compared with those in the first sample from an individual patient. The Spearman correlations between the relative changes in concentrations of IL-6 and IL-8, IL-6 and TNFα, IL-6 and lactoferrin, and IL-8 and lactoferrin were significant (n = 19, p < 0.05), whereas the correlation between the relative changes in concentrations of IL-6 and IL-1β were not (n = 19, p > 0.2) (table 3).

**Discussion**

We examined the relationship between IL-6 and other proinflammatory cytokines, and neutrophil chemotaxis and activation in synovial fluids of rheumatoid arthritis patients, in order to analyse to what extent IL-6 concentrations in SF reflect those of other factors believed to be the main causes of bone and cartilage destruction in inflammatory arthritis.

We have confirmed previous reports of high concentrations of IL-6 in SF of patients with RA. Our study comprised only patients with early RA, but no comparison of data related to disease duration could be made because most published studies did not mention the stage of the disease. Because previous studies used different methods or expressed results in arbitrary units and did not afford appropriate comparisons, we have compared three assays—a bioassay, a commercially available ELISA and one which is not commercially available—and have expressed our results in ng/ml, calibrated against a recombinant hu-IL-6 standard. Despite the use of different antibodies, no differences were found between the results of the two immunoassays. In addition, IL-6 concentrations as measured with the immunoassays and the bioassay were similar, at both high and low ranges of detection, indicating that IL-6 detected with these assays was both specific and biologically active.

Several investigators have tested SF for the presence of IL-1β and have obtained conflicting results, depending on the method used. Most bioassays could not demonstrate IL-1, which was attributed, in part, to the presence of inhibitors such as IL-1 receptor antagonist. Our inability to demonstrate the presence of IL-1β with the EASIA (Medgenix) was in sharp contrast with the results obtained with the ELISA (Cistron). This contradiction appears not to be merely a consequence of differences in sensitivity of the assays: in about 50% of the samples the concentrations measured with the ELISA (Cistron) were >50 pg/ml and thus above the detection limit of the EASIA (Medgenix). Differences in reagents or in sensitivity to cross-reacting substances in SF may have contributed to differences between results from the two respective assays. Our ELISA (Cistron) results agree with those from other studies which used reagents from the same manufacturer.

Using an immunoassay having a sensitivity as low as 15 pg/ml and no known interference by soluble receptors, we detected TNFα in all our SF samples. Taking into account the differences in detection limits of the assays used in other studies, our results are in agreement with those reported previously. Although the local production of GM-CSF in rheumatoid synovitis has been demonstrated by several investigators, very few data concerning GM-CSF concentrations in SF have been published. Xu et al. demonstrated GM-CSF-like activity in RA SF, but could not...
detect immunoreactive GM-CSF in SF using a radioimmunoassay with a sensitivity of 100 pg/ml. This in contrast with their results from synovial tissue culture supernatants, in which GM-CSF could be identified both with the radioimmunoassay and with a bioassay. Despite using a more sensitive immunoassay (detection limit 25 pg/ml), we were not able to detect GM-CSF in any of the RA SF samples (n = 61). Using the same assay, we had been able to demonstrate GM-CSF in concentrations of 25–200 pg/ml in serum samples of an RA patient with Felty syndrome treated with recombinant human GM-CSF,13 and in supernatants of IL-1 stimulated fibroblast and RA synoviocyte cultures (data not shown).

IL-8 has been shown to be a potent chemotactic factor for PMNL. In our sensitive chemotaxis assay (CTI ≥ 2%), the minimum concentration of recombinant-human-IL-8 for detection of chemotaxis was 0.4 ng/ml, resulting in a lower detection limit in SF (dilution 1:10) of 4 ng/ml. In our study the concentrations of IL-8 in SF were in the range 0.2–36 (median 1.0) ng/ml. We found a weak correlation between IL-8 concentration and lactoferrin concentrations may be considered to be representative of those in vivo.

The contribution of these cytokines to this activation or lysis of PMNL in vitro, so the chilling and rapid cell separation, does prevent this difference of GM-CSF is not clear from this study, as IL-1 is thought to be one of the major inducers of both IL-6 and IL-8. The concentration of IL-1 in SF reflects both local production and local consumption of IL-1: the biological availability of IL-1 depends on the simultaneous production of IL-1 receptor antagonist (IL-1 RA)6 and the change in balance between IL-1 and IL-1 RA over time. The same may be true for TNFα and soluble TNF-receptors.6,7 However, it is not clear if the inhibitors of IL-1 and TNFα have a comparable biological role.

It can be concluded from the present results that IL-6 in SF of RA patients may be considered as an indicator for local proinflammatory and potentially erosive activity of proinflammatory cytokines, and PMNL activation. This supports the earlier findings that serum concentrations of acute phase proteins such as CRP, which are induced by IL-6, are related to the progression of radiologically demonstrable joint damage.11

We thank J Bijlsma, R van Wijk and W Lokorna for technical assistance. EASIA reagents were kindly provided by D Radoux, Madgenis, Brussels, Belgium. Dr J. Arndt, C.I.R. Amsterdam, kindly provided the mouse hybridoma cell line B9, and MAb IL-6-16 and 5b-8-IL-6 antibodies.

This study was supported by a grant from Het National ReumaFonds of The Netherlands.
