**Abstract**

Hypokalaemic periodic paralysis (HypoPP) is characterised by transient attacks of muscle weakness of varying duration and severity accompanied by a drop in serum potassium concentration during the attacks. The largest known HypoPP family is of Dutch origin and consists of 277 members in the last five generations, 55 of whom have HypoPP inherited in an autosomal dominant pattern. Forty-eight persons including 28 patients with a proven diagnosis of HypoPP were used for linkage analysis. Microsatellite markers were used to exclude 45 to 50% of the genome and linkage to chromosome 1q31–32 was found. No recombinants were found between HypoPP and D1S412 and a microsatellite contained within the DHP receptor α1 subunit (CACLN1A3) gene. A previously reported G to A mutation causing an arginine to histidine substitution at residue 528 in the transmembrane segment II S4 of the CACLN1A3 gene was shown in patients by restriction analysis of genomic PCR products.

**Material and methods**

The family has 277 members in the last five generations, 55 of whom have HypoPP. Fourty-five affected persons were alive at the start of the investigations and 33 were personally investigated by one of the authors (TPL). Nineteen patients had typical attacks, myotonia, paramyotonia congenita, and atypical myotonia congenita are all known to result from mutations at various sites in the gene coding for the α1 unit of the adult isoform of the skeletal muscle sodium channel (SCN4A) on chromosome 17q. HypoPP (MIM 170400) is the most frequent form of periodic paralysis. Although it is usually transmitted as an autosomal dominant disease, sporadic cases do occur. The initial attacks typically occur during the first two decades of life, sometimes increasing in frequency to weekly or even daily occurrences, but decreasing in frequency over the age of 30. Permanent muscular weakness on the basis of a vacuolar myopathy develops in some people and may lead to severe disability in older patients. The pathophysiology of HypoPP has not been elucidated. An increased transmembrane conductance of Na⁺, increased activity of the sodium potassium pump, and faults in K⁺ conductance have been proposed as the basic defect. However, even detailed neurophysiological in vitro investigations of muscle fibres have not provided an adequate explanation.

We were investigating the largest known HypoPP family for linkage when the assignment of the HypoPP locus to chromosome 1q31–32 was published. The data of Fontaine et al. suggest genetic homogeneity and the DHP receptor (calcium channel) alpha 1 subunit (CACLN1A3) as a candidate gene and recent studies have indeed shown mutations in this gene. In the present study we confirmed linkage to 1q31–32 and were able to pinpoint a specific mutation in the CACLN1A3 gene.

while 14 had muscle weakness without attacks.11 The diagnosis of HypoPP was based on clinical history, neurological examination, and a reduced muscle fibre conduction velocity.20 The diagnosis was based on the clinical history and notes from other hospitals in the remaining cases and in dead patients.10,11 The mean age of onset of attacks was 15.6 (range 11-19) in men and 14.9 (range 9-18) in women. Forty-eight persons including 28 patients, all over the age of 20, were used for linkage analysis (fig 1). An autosomal dominant mode of inheritance was noted in the family. If the criteria mentioned above are used for diagnosis, the disease has complete penetrance.10,11

DNA ANALYSIS
Blood samples were collected from 48 persons and genomic DNA was isolated by phenol-chloroform extraction.31 Typing of microsatellite markers was performed as previously described.22,23 Microsatellite markers from the Dutch Microsatellite Marker Collection23 were used for the random gene search. For confirmation of linkage to chromosome 1q31-32, the following markers were used: D1S158, D1S53, D1S412, D1S413, D1S249, and CACNL1A324,25; primer sequences are available through the Human Genome Data Base. PCR reactions were done on 50 ng of template DNA with α32P-CTP in a volume of 15 µl in 96 well microplates as previously described23 except that end labelling of one of the primers was used for the CACNL1A3 marker. After electrophoresis, the gels were dried and exposed overnight to x ray film (Kodak X-AR).

LINKAGE ANALYSIS
Two point and multipoint lod scores were computed with the LINKAGE program package version 5.10,26,27 HypoPP was considered to be autosomal dominant with a penetrance of 100%. The frequency of the gene in the general population was estimated as 0.0001.17

MUTATION SCREENING
The G to A mutation in codon 528 of the CACNL1A3 gene causes the loss of a BbvI restriction site.19 Genomic DNA was amplified by PCR with the forward primer 5'-GGAGATCCCTGCTGGTGAGTCG-3' and the reverse primer 5'-TCCTCAGGAGGCGGTGCGAC-3' according to the protocol of Jurkat-Rott et al.10 After digestion with BbvI, the PCR products were run on a 15% polyacrylamide gel. Normal controls show two bands of 44 bp and 33 bp; mutants show an additional band of 77 bp, representing the undigestable PCR product.

Results
At first, candidate regions containing ion channel or related genes were examined to exclude
Paired lod scores between chromosome 1q markers and HypoPP

Haplotype analysis showed several recombination points between HypoPP and D1S158 and D1S53, but not with D1S412 and the microsatellite located within the CACNL1A3 gene. Recently Jurkat-Rott et al.39 found a G to A mutation in the transmembrane segment II.S4 in several independent HypoPP patients. This mutation was also found in our Dutch HypoPP family.

Discussion

Because this is the largest known family with HypoPP, our finding of linkage of HypoPP to chromosome 1q31-32 strongly supports the data of Fontaine et al.34 The penetrance of the gene defect appears to be complete, although the age of onset varies and the clinical manifestation may be permanent and progressive muscle weakness instead of paralytic attacks.35
