The excised skin tumour, measuring 55x25x25 mm, was ulcerated, nodular, and crusted. On section, the tumour was well circumscribed and had a chalky white appearance with small foci of calcification (Fig 2). Histological examination showed two main cell types; basophilic cells located peripherally in cell islands and showing occasional mitotic figures and eosinophilic shadow cells, found towards the central areas of the cell masses, with no nuclear staining. Intervening stromal component composed of blood vessels and a scattering of mixed inflammatory cells. Overall, the features were those of benign pilomatrixoma, which was well circumscribed and appeared to have been completely excised. The wound healed very satisfactorily without further surgery, and she was pleased with the cosmetic result.

COMMENT

The tumour in the case presented was of uncertain diagnosis clinically, partly as a result of the patient's age. Differential diagnosis included basal cell carcinoma, squamous cell carcinoma, keratoacanthoma, and neurofibroma. Other less typical aspects of this case were the rapid growth rate and large size of the tumour. In view of the possibility of malignancy, it was felt to be important to establish a histological diagnosis. Incisional biopsy, if small, could have led to a misdiagnosis of basal cell carcinoma, owing to the pleomorphism of pilomatrixoma with basophilic cells present peripherally, and would have required subsequent definitive surgery. We opted for excision biopsy with a narrow margin of clearance as the primary procedure.

Once the lesion was established as benign, no further surgery was necessary and the wound healed by secondary intention. Had the lesion proved malignant, secondary wider excision of the wound margins would have been required, probably with skin grafting to repair the larger defect once the margins were clear. Mohs' surgery would have been an alternative but lengthy procedure.

We endorse the advice of Simpson et al.2 regarding the importance of making a tissue diagnosis before undertaking definitive surgery in cases such as this, where the clinical diagnosis and nature of the lesion are uncertain. Thus, for benign hair follicle tumours, wide margins of excision are avoided although for the common basal cell carcinoma they would be required. Notably, over a 30 year period at the Institute of Ophthalmology, there were 2447 cases of basal cell cancers compared with 94 cases of pilomatrixoma.2

Less commonly, giant pilomatrixoma has been described which behaves more aggressively and shows rapid growth rate and larger size, the latter features shared with this case.4 5 Pilomatrix carcinoma occurs rarely and is diagnosed on the basis of frequent mitoses in the basaloid cells and invasion of adjacent fat, muscle, and blood vessels.6

The case reported here serves as a reminder that pilomatrixoma has a predilection for the upper eyelid or eyebrow and may occur at any age, although it is commoner in children. If these cases are to be spared the greater cosmetic disfigurement of wide margin excision the importance of first establishing a diagnostic biopsy is re-emphasised.

Ectopic teeth in the orbit of a neonate

EDITOR,—Congenital orbital teratomas are rare tumours derived from more than one germinal layer.1 The inclusion of dental elements in such an orbital tumour has rarely been reported as a bizarre finding.2 3 We encountered an unusual primary orbital teratoma with presence of mature dental elements in the orbit and preservation of good visual function after surgery.

CASE REPORT

A full term baby boy was born following an uneventful pregnancy and vacuum delivery. He was small for dates and developed jaundice for which he was treated in hospital. During his stay some proptosis of the right eye was noted. No pupillary or motility disturbance occurred to a varying degree. In a bizarre case, described by Mizuo and cited by Kivelä and Tarkkanen,4 the inclusion of dental elements (squamous epithelium, epithelium with basaloid features, teeth incisors which show differentiation corresponding to the age of the patient), and mesoderm (prominent connective tissue, bone fragments).

Twelve months postoperatively the child exhibits only slight ptosis and slightly reduced elevation of the right eye. There was no afferent pupillary defect and visual acuity was equal to the contralateral eye as measured with the Bock candy bead test.

COMMENT

The orbit is a rare, but well known location of congenital teratoma. These choristomas are composed of tissues of at least two germinal layers. Tissue types present in the lesion may be differentiated to a varying degree. In a bizarre case, described by Mizuo,3 and cited by Kivelä and Tarkkanen4 a teratoid fetus was found. Tissue differentiation to a mature degree is unusual.

Orbital teratomas are usually present at birth, although adult cases have been described. The neonate typically presents with moderate (but obvious) to massive proptosis and its sequelae, such as lagophthalmos and corneal ulceration.5 Ocular motility is markedly reduced, whereas visual function is very poor. One case has been described in which useful vision was preserved.6 The salvage of vision, and indeed the eye, is related to the age of the tumour. Management used to comprise exenteration, although the introduction of microscopic
operative techniques has resulted in less aggressive treatment with preservation of the eye.

Our case demonstrates some unusual features of orbital teratoma. The presence of globe displacement was not very obvious with the eye closed. In the presence of tumour mass in the orbital apex, ocular movements were still full, whereas visual function did not appear to be severely reduced. Following complete excision of the tumour, vision had not changed clinically. A high index of suspicion in the presence of a cystic lesion in the neonate, even in the absence of obvious proptosis, particularly in the presence of calciﬁcations, may lead to the diagnosis of orbital teratoma. Surgery by a route allowing complete excision should be planned as soon as possible.

Orbital coccidiomycosis presenting as a lacrimal gland fossa mass

EDITOR—A wide spectrum of pathologic processes such as tumour, infections, and inﬂammatory diseases can present as a mass in the superotemporal orbital region. The clinical history and radiographic ﬁndings often provide the clues necessary for diagnosis and planning of treatment. Here, we report an unusual case with a lacrimal gland fossa mass caused by Coccidioides immitis, a fungus endemic to the southwestern United States, Mexico, and Central and South America.

CASE REPORT
A 36-year-old Filipino man with no history of head trauma presented with a 2 week history of pain and proptosis of the right eye, accompanied by intermittent fevers and chills. Medical history was signiﬁcant for a mild pneumonia 6 months previously that had resolved after treatment with oral antibiotics. On examination, there was lid erythema and oedema with tenderness of the right upper lid. Visual acuity was 20/20 in each eye, and anterior and posterior segments appeared normal. Hertel exophthalmometry measured 19 mm in the right eye and 14 mm in the left eye. His blood proﬁle revealed a mild leucocytosis (WBC 12.5 x 10⁹ /L) cells), an elevated erythrocyte sedimentation rate (ESR) by Westergren of 44 mm in the ﬁrst hour, and an antinuclear antibody (ANA) titer of 1:320. Rapid plasma reagin (RPR) and human immunodeﬁciency virus (HIV) titres were negative. Chest x ray revealed no evidence of hilar lymphadenopathy or mass. Computed tomography (CT) scan of the orbit and brain revealed a mass in the right lacrimal gland fossa that displaced the globe downwards and forwards with thickening of the adjacent lateral rectus muscle. The preop osive subcutaneous tissue was oedematous, and there was temporal extension of the soft tissue swelling (Figs 1A and 1B). A presumptive diagnosis of bacterial orbital cellulitis was made and systemic antibiotic treatment with biotics (Unasyn (ampicillin with sulbac tam) mimic the CT ﬁndings in idiopathic orbital cellulitis. The proptosis responded favourably within 24 hours, and he was discharged on day 10 with Augmentin (co amoxiclav) 500 mg orally three times a day, and prednisone 80 mg once a day. However, 4 days after discharge, he complained of recurrent right eye pain and a ﬂuctuant mass was noted over the right forehead; 12 ml of brownish pus was recovered by aspiration. The smear revealed yeast forms, and cultures grew Coccidioides immitis. Computer tomography of the orbits showed an increase in the preop osive subcutaneous mass (Fig 2). The prednisone was stopped and the patient was readmitted for treatment with amphotericin B (50 mg intravenously every day for 3 weeks). Oral fluconazole (800 mg/day) was used as a maintenance agent upon discharge. One year after the initial presentation, the patient remained asymptomatic and a repeat CT scan of the orbit was performed which revealed resolution of the mass.

Figure 1 Computed tomography scans of the orbit before corticosteroid treatment but after intravenous antibiotics. Axial views, increase in subcutaneous mass (arrow) compared with that shown in Figure 1A.

Figure 2 Computed tomography scans of the orbits after corticosteroid treatment but before intravenous antibiotics. Axial views, increase in subcutaneous mass (arrow) compared with that shown in Figure 1A.

COMMENT
Coccidioidomycosis is a pathogenic, endemic fungal disease caused by the organism Coccidioides immitis. The ocular manifestations of coccidioidomycosis are many and can involve certain extraocular or intraocular tissues. However, to our knowledge lacrimal gland invasion by the organism has not been reported previously. Our patient presented with a painful proptosis suggestive of a bacterial orbital cellulitis, for which he was treated with intravenous antibiotics. The tentative diagnosis of dacryo adenitis was based on the moderate improvement with intravenous antibiotics and the CT scan ﬁndings which were consistent with an inﬂammation of the lacrimal gland. The usual incidences of lacrimal gland masses are benign mixed tumour (12%), dacryocele (6%), malignant epithelial tumours (4%), inﬂammatory pseudotumour (idiopathic orbital inﬂammation) (50%), sarcoi d (13%), lymphoid masses (13%), and acute dacryoadenitis (1%).

Orbital infections that involve the lacrimal gland initially produce only non-speciﬁc inﬂammatory changes on CT scan, such as thickening of the scleral-wal eva rim, enhancement of the lacrimal gland, or thickening of an extraocular muscle, changes that often mimic the CT ﬁndings in idiopathic orbital inﬁammation in the lacrimal gland region. An abscess can be clearly delineated by CT scan only when necrotic tissue is present within encapsulated ﬁbrous tissue. Since a CT scan may not reveal an abscess during the initial presentation, orbital ultrasound has been recommended when an abscess is suspected. In a review of 15 cases with orbital abscess, ultrasound consistently revealed well deﬁned lesions of low internal reﬂectivity with high reﬂective borders. Balchunas et al examined 32 patients with lacrimal gland/fossa masses who had CT scans and/or standardised A-mode echography (SAE), and con cluded that the initial examination of a lacrimal gland/fossa mass should begin with SAE since its speciﬁcity exceeds that of CT scans in this region. However, many orbital surgeons prefer to rely on CT scanning.

The current treatment of choice for ocular coccidiomycosis is intravenous amphot ericin B, which has been proved to be effective in the treatment of extrapulmonary dissemination of Coccidioides immitis. Drainage is indicated if the abscess is large or if it is...
