Multiple reflex sympathetic dystrophy. Which patients are at risk for developing a recurrence of reflex sympathetic dystrophy in the same or another limb

Peter H.J.M. Veldman * and R.Jan A. Goris
Department of Surgery, University Hospital Nijmegen, Nijmegen, (The Netherlands)

Summary
Many aspects of bilateral presentation or recurrence of reflex sympathetic dystrophy (RSD) are unknown. For this reason 1183 consecutive patients with RSD were analyzed. In 10 patients RSD started in symmetrical limbs. In 34 patients RSD recurred in the same limb after a period of no or few complaints and in 76 patients RSD recurred in one or more limbs other than the first limb. Compared to 1065 patients with RSD without these features, these patients were younger (P < 0.01) and RSD started more frequently with a cold skin temperature (P = 0.02). Patients did not differ in gender or primary localization of RSD. Involvement of a second limb concerned in 47% the symmetrical limb. Recurrences were in 53% of spontaneous origin and often characterized by few signs and symptoms. The incidence of a recurrence was 1.8% per patient per year. No measures are known to prevent recurrence. Reflex sympathetic dystrophy may recur in the same or in another limb, although only in a minority of patients. Recurrences occur especially in younger patients and in the symmetrical limb. Diagnosis of a recurrence is difficult, for often the recurrence is spontaneous and presents with few signs and symptoms.

Key words: Reflex sympathetic dystrophy; Sudeck atrophy; Shoulder-hand syndrome; Algodystrophy; Sympathetically maintained pain

Introduction
Reflex sympathetic dystrophy (RSD) is an abnormal reaction of the body to trauma and one of the most frequent complications after surgery to extremities. RSD is characterized by pain, edema, vasomotor changes, loss of function and increase of these signs and symptoms after exercise. Several other signs and symptoms, such as neurologic disturbances, hyperhidrosis and atrophy may also occur (Veldman 1993). The signs and symptoms are localized in the periphery of a limb. In the upper limb there may be concomitant complaints of the shoulder, known as the shoulder-hand syndrome (Steinbrocker 1968; Veldman 1995). Some authors report patients with RSD localized around a knee (Ogilvie-Harris 1987), hip (Acquaviva 1982), in the thoracic wall (Ivey 1991) or in the face (Veldman 1994), although these presentations are rare.

Recurrence of RSD after a period of no or few complaints or localization in more than one limb has been reported in French literature concerning algodystrophy (Evans 1947; Doury 1973; Serre 1973; Acquaviva 1982; Riffat 1986), although their diagnostic criteria are different from what is called reflex sympathetic dystrophy in Anglo-Saxon literature. For instance, in French literature several patients with a painful osteoporosis without other signs and symptoms are diagnosed as RSD. In English literature, these features have been the subject of a few case reports or – when presented in a series of patients – as a matter of secondary importance. Still many patients ask us when...
they are discharged from further therapy – cured or not cured – “Can it recur?”. Both aspects – localization of RSD in multiple limbs and recurrence of RSD in the same or another limb – are the subject of this report.

Patients and methods

In November 1984 an outpatient clinic for RSD patients was instituted by the Department of Surgery of the University Hospital Nijmegen. Since then, we have seen approximately 1500 patients – mostly referred from other departments or hospitals – with a presumed or suspected diagnosis of RSD.

RSD has not been clearly defined in literature. The criteria for diagnosis are:

1. 4 or 5 of following symptoms:
   - unexplained diffuse pain
   - difference in skin color in relation to the healthy symmetrical limb
   - diffuse edema
   - abnormal skin temperature in relation to the healthy symmetrical limb
   - limited active range of motion
2. Above signs and symptoms increase during exercise
3. Above signs and symptoms are present in an area much larger than the area of primary injury or operation and including the area distally of the primary injury.

These selection criteria approximate those utilized in other studies concerning RSD (Kozin 1981; Christensen 1982; Poplawski 1983; Atkins 1990) and are discussed in a previous report (Veldman 1993).

Special attention was paid to signs and symptoms, localization and etiology of RSD. If no luxating events, even minor trauma, could be remembered by the patients, the RSD was considered to be of spontaneous origin when the patient could not remember any injury.

Results

During the study period (November 1984 to April 1994) 1183 patients fitted into the above criteria for RSD. One thousand and sixty-five patients were seen with a single episode of RSD in one limb (further called single RSD). In 118 patients (10%), history or follow-up revealed presentation of RSD in two limbs or a recurrence of RSD in the same or another limb (further called multiple RSD) (Table I). When all secondary presentations of RSD in time or in another extremity were counted separately, there was a total of 136 recurrences.

The group with single RSD consisted of 267 male (25%) and 798 female (75%) patients (Table II). Age varied from 4 to 84 years (median 41 years). RSD was localized in the upper limb in 635 patients (60%), and in 430 patients (40%) in the lower limb. In 105 patients (10%) RSD was of spontaneous origin (Table III). RSD was considered to be of spontaneous origin when no signs of precipitating disease or injury were present and the patient could not remember any injury.

The group of 118 patients with multiple RSD consisted of 23 male (20%) and 95 female (80%) patients (Table II). Age at time of onset of RSD varied from 9 to 71 years (median: 35 years). The first localization of RSD was in the upper limb in 58 patients (49%) and in the lower limb in 60 patients (51%). In 72 of all 136 recurrences (53%), the recurrence or the affection of another limb developed spontaneously (Table III).

Comparing the patients with single versus multiple RSD, no difference was found as to gender or the first localization (Table II). Patients with multiple RSD were younger (Kruskal-Wallis: \(P < 0.01\)).

Nine hundred and forty of the RSD patients could remember which difference in skin temperature existed between the diseased and the healthy symmetrical limb at the time complaints started (warm, cold or same temperature: primary temperature). In the multiple group, 49 out of 94 patients (52%) told us that the skin temperature was colder, in contrast to 317 out of 846 (38%) in the single group (\(P = 0.02\); chi-square, Yates corrected).

In 10 patients, RSD started simultaneously in 2 limbs; these were always symmetrical limbs. In 5 of

In 34 patients, RSD recurred in the same limb after a period of no or few complaints. Time between first and second appearance varied from 3 months to 20 years (median: 2.7 years). Patients with a recurrence in the same limb did not differ from patients with a recurrence in another limb, as to gender, etiology of primary RSD, primary temperature or affected extremity, but patients with a recurrence in the same limb were younger (Kruskal-Wallis: \( P = 0.01 \)). In 64 patients RSD recurred in a second limb. When RSD recurred in a second limb this concerned the symmetrical limb in 30 of 64 patients (47%); in 34 patients (53%) primary RSD and recurrence concerned 1 upper and 1 lower limb; 18 times on the same side (hemiplegic distribution), 16 times on opposite sides. Eight patients suffered from RSD in 3 limbs. Because of intractable pain and total incapacitation, one of these patients committed suicide. Four patients suffered from RSD in all 4 limbs.

Discussion

Recurrence in the same limb

Recurrences of RSD in the same limb have been reported by Evans (1947). He mentioned exacerbations of RSD after surgery or infection but did not present any details concerning development of the syndrome. In French literature several studies report recurrences. As mentioned before, we must make some reservations because diagnostic criteria are not the same in French and Anglo-Saxon countries. Acquaviva et al. (1982) reported 32 patients with a recurrence of RSD in their presentation of 765 patients (4%) and Gougeon et al. (1982) reported 41 recurrences in 573 patients (7%); both studies did not report the duration of follow-up.

Bilateral RSD

Bilateral presentation of RSD has been reported before. Livingstone (1943) reported “mirror images” in 35 patients with bilateral RSD, as the affection was always located in symmetrical areas of symmetrical extremities. Other studies on bilateral RSD found no such mirror images (Kahlmeter 1930; Johnson 1943; Rosen 1957; van der Korst 1967; Koizin 1976; Subbarao 1981; Poplawski 1983). In the present series, no mirror images were seen but bilateral presentation was found in 10 patients and recurrences concerned the symmetrical limb in 47% of cases.

Complaints in the symmetrical limb without clinical signs and symptoms of RSD have been reported before. Koizin et al. (1976) reported 11 patients with a shoulder-hand syndrome. One of their patients showed clinical signs and symptoms of RSD in both arms and another patient in 1 arm and 1 leg. In 8 patients they found an increased number of painful joints in the symmetrical limb without other signs and symptoms of RSD. Kurvers et al. (1992) reported increased red blood cell velocity (RBCV) in patients with warm RSD. 74% of these patients showed increased RBCV in the symmetrical limb without signs and symptoms of RSD. In cold RSD they found decreased RBCV, and in 30% of these patients RBCV in the symmetrical limb was decreased without signs and symptoms of RSD. Such measurements in other than the symmetrical limbs have, to our knowledge, not been performed.

Bhatia et al. (1993) reported spreading to other limbs in 7 of 18 patients with both RSD and dystonia. Secondary involvement concerned the symmetrical limb in 3 and the homolateral limb in 4 patients. Localization of RSD in 3 or even 4 extremities is extremely rare and known from case reports only (Bentley 1990; Barrera 1992; Schieffenbauer 1993).

In 53% of our patients, no luxating factor could be related to the recurrence of RSD. Acquaviva et al. (1982) reported 32 recurrences in 765 patients with RSD, without a luxating factor in more than 50% of the patients. Gougeon et al. (1982) also reported a high incidence of spontaneous origin in recurrences but did not present details. The high frequency of spontaneous recurrence of RSD, and the onset of recurrent RSD at a younger age, suggest that these patients are predisposed for developing RSD.
No other reports on the incidence of recurrent RSD in the same or other limb could be found. Once a patient has developed RSD, the incidence of recurrence of RSD is 1.8% per year. In this study 10% of the patients developed a recurrence of RSD and in the future more patients will probably develop another episode of RSD. From this study we conclude that young patients in which RSD started with a cold skin temperature have the highest chances for experiencing a recurrence.

Preventive measures for recurrences of RSD are unknown. Many physicians expect trauma or surgery will reactivate the syndrome, although this hypothesis has never been proven in a prospective study. As the incidence of recurrence is low and as more than 50% of the recurrences of RSD are of spontaneous origin, we do not advise our patients to take any special measures for preventing trauma.
