Relationship between respiratory muscle function and quality of life in sarcoidosis

ABSTRACT: In sarcoidosis, pulmonary and general symptoms often do not correlate with radiographic stage and routinely performed lung function tests. Asymptomatic muscle involvement in sarcoidosis is common, but little is known about respiratory muscle involvement. The aim of this study was to investigate any relationships between persistent complaints and/or quality of life and respiratory muscle strength and endurance.

Measurements of maximal inspiratory and expiratory mouth pressures (Pi,max and Pe,max), respiratory muscle endurance and routine lung function were made in 18 patients with sarcoidosis. To assess health status and quality of life, patients completed the Sickness Impact Profile (SIP).

Respiratory muscle strength and endurance time were lower in the patient group than in a group of healthy controls (p<0.05). Compared to a general population, the patients with sarcoidosis were found to be limited in physical and psychosocial functioning. The respiratory muscle endurance time correlated with the SIP subscales "mobility" (r=-0.56; p<0.01), and "body care and movement" (r=-0.79; p<0.001). The total lung capacity (TLC), inspiratory vital capacity (IVC) and forced expiratory volume in one second (FEV1) were normal in all subjects.

In conclusion, patients with sarcoidosis and normal lung function showed reduced respiratory muscle strength and endurance time. Correlations were found between these indices and both symptoms and certain Sickness Impact Profile domains. Therefore, we suggest inclusion of measurements of respiratory muscle strength in the assessment and follow-up of patients with sarcoidosis.

Sarcoidosis is a multisystem disorder, which can affect essentially every organ of the body [1]. The parts of the body most frequently involved are the lungs, lymph nodes, skin, eyes, muscles, heart and joints, and, therefore, symptoms vary considerably. In sarcoidosis, disease activity does not necessarily indicate a progressive or fatal course [2]. Even though the active disease often subsides spontaneously, an indication of activity is necessary in order to monitor the course of the disease and to guide treatment, should the clinical situation justify it [2, 3]. Whilst there is no single test that accurately reflects the progression of sarcoidosis, clinical examination, chest radiography and lung function tests are used to evaluate and monitor the disease process. Techniques useful in assessing the extent and severity of granulomatous inflammation and fibrosis are: 1) serum markers, including serum angiotensin converting enzyme (sACE); 2) 62Ga scan; 3) bronchoalveolar lavage (BAL); and 4) high resolution computed tomography (HRCT) [2, 4]. When indicators of disease activity, such as radiographic abnormalities, lung function impairment and sACE, return to normal, nonspecific symptoms, such as fatigue and reduced exercise tolerance, may persist.

In a previous study, we found that the quality of life measured by the Sickness Impact Profile (SIP) was related to the perception of complaints, but not to disease activity as conventionally assessed [5]. The SIP is a generic health status instrument, which is intended to measure the impact of sickness rather than to objectively measure the presence of disease [6]. It is an individual's own experience of illness perceived through its effect on daily activities, feelings and attitudes [7].

Asymptomatic granulomatous muscle involvement in sarcoidosis has been reported with a prevalence of 50–80% [8], whereas symptomatic muscle involvement is much less common (range 1.4–2.3%) [9]. The symptomatic involvement that has been described varies from a palpable nodular type to an acute myositis, and a chronic myopathic type [9–12]. Usually, patients present with pain, weakness and muscle atrophy [13]. Little is known, however, about the frequency of respiratory muscle involvement [14].

The aim of this study was to investigate whether there is a relationship between persistent complaints or quality of life disturbance and respiratory muscle function in a population of patients with sarcoidosis. Therefore,
the relationships between respiratory muscle strength, endurance time, and the SIP scores and subscores were evaluated.

Materials and methods

Subjects

Eighteen out-patients suffering from sarcoidosis, who attended the Academic Hospital Nijmegen, were studied. The diagnosis of sarcoidosis was based on consistent clinical features, together with biopsy-proven noncaseating epithelioid cell granuloma. The clinical symptoms of the respective patients varied from none (sarcoidosis detected on routine chest radiography) to more or less severe respiratory symptoms or erythema nodosum and arthralgia (i.e., Lofgren's syndrome). None of the participating subjects had any significant medical history that might have influenced quality of life. Patients with significant co-morbidity were excluded.

A control group (n=18), comprising healthy employees of the Academic Hospital Nijmegen matched for age and gender, were used as reference for the lung function tests, respiratory muscle strength and endurance time, as well as peripheral muscle strength. A control group comprising 594 subjects from a general Dutch population (mean age 43 yrs, range 18-75 yrs; 267 males (45%) and 327 females (55%)) were used as reference to compare the SIP measurements [15].

Study design

Initially, 26 patients with sarcoidosis were contacted. Eight declined for various personal reasons. Eighteen patients agreed to participate after giving informed consent. The questionnaires were completed under supervision of a study assistant, to avoid missing data or misunderstanding. In addition, the patients were asked about their smoking history and whether they had any of the following complaints: fatigue, dyspnoea, cough, arthralgia, or erythema nodosum.

At the time the study was performed, seven of the patients still had symptoms, most notably fatigue. Eleven of the 18 patients had not taken corticosteroids during the previous 3 months. The other seven patients were taking corticosteroids during the 3 months prior to the study, with an average prednisone dose of 5.7 mg·day⁻¹. Five of these seven patients still had symptoms. The mean (±SD) sACE level was 16.8±5.9 U·L⁻¹ (reference value <20 U·L⁻¹). The radiographic stage varied from 0 to III: four patients had stage 0, two stage I, 10 stage II, and two stage III appearances. Demographic and clinical characteristics of the patients and the control group are summarized in table 1.

Lung function tests

Lung function measurements included forced expiratory volume in one second (FEV₁), inspiratory vital capacity (IVC) measured with a pneumotachograph, and total lung capacity (TLC) measured using a body plethysmograph (Compactbody; Jaeger, Würzburg, Germany). The best of three efforts was selected. All volumes were expressed as percentages of the reference values [16].

The transfer factor of the lung for carbon monoxide (TLCO) was measured by the single-breath method (Masterlab; Jaeger, Würzburg, Germany). In order to compare the TLCO level with the quality of life scores, the values were classified into four ranges: 1) normal (≥80%); 2) mild decrease (60–80%); 3) moderate decrease (40–60%); and 4) severe decrease (<40% of predicted), according to the American Medical Association classes.

Respiratory muscle strength and respiratory muscle endurance

Inspiratory and expiratory muscle strength were assessed by measuring maximal respiratory mouth pressures using the method of Black and Hyatt [17]. Maximal inspiratory mouth pressure (PI,max) was measured at residual volume (RV), whilst maximal expiratory mouth pressure (PE,max) was measured at total lung capacity (TLC). The equipment used was a pressure transducer (model MP 45-30; Validyne Engineering Corp., Northridge CA, USA). All signals were recorded on a strip chart (type BD 31; Kipp & Zonen, Delft, The Netherlands). A needle was placed in the proximal end of the mouthpiece to ensure that efforts were performed with open glottis. At least five manoeuvres were performed, until the three highest values were within 5% of each other. All subjects were seated in the upright position and were wearing a noseclip while performing the tests, and the same instructions were given to each subject by one investigator. Values are expressed in absolute terms and as percentages of predicted values according to Wilson et al. [18].

Respiratory muscle endurance was assessed by measuring the endurance time using a modified threshold loading device as designed by Nickerson and Keens [19]. This device has an inspiratory valve, which can be occluded by a weighted plunger. The plunger can be adjusted externally so that patients must generate enough inspiratory pressure to lift the inspiratory valve and allow inspiratory flow.Expiration can be performed without any resistance. The threshold loading device was first tested and validated in healthy subjects before use. There was a very close relationship between the inspiratory pressure (Pᵢ) generated and external weight (W) (Pᵢ=(0.201126xW + 7.4659); r=0.999, p<0.001; Pᵢ in cmH₂O, W in g). The respiratory muscle endurance time was defined as the maximal time (in seconds) during which a subject could sustain breathing against an inspiratory pressure load equal to 70% of his/her individual PI,max [20]. All subjects first warmed up by breathing against an inspiratory pressure load equal to 15% of their PI,max during 2 min. Next they were presented with their individual test load and instructed to breathe for
Peripheral muscle strength

Quadriceps force was measured on the nondominant side with the subject sitting, both hip and knee in 90° flexion, the ankle connected to measuring-equipment based on strain gauges. A nonstretching-band was placed around the hip to prevent the subject from lifting up whilst pulling away the lower leg. The force of the hand muscles was also measured on the nondominant side with the subject sitting, the forearm and hand in a direct line with each other and resting on a table, and the fingers enclosing two wooden handles connected to the measuring equipment based on strain gauges. In both tests, at least three isometric contractions were performed until the differences were not more than 5%. Between each effort there was an interval of 1 min. Values are expressed as kilogram force (kgf).

Health status questionnaire

Health status and quality of life were assessed with the SIP (Dutch version) [15, 21]. The SIP was designed to assess sickness-related behavioural dysfunction. It provides summary scores for physical, psychosocial, and overall behavioural dysfunction, as well as separate scores for 12 categories of activity. The scores range between 0 and 100. The higher the scores, the stronger the impact of the disease on the individual's life.

Statistical analysis

The data of the control subjects and patients were compared using Student's t-test for binomial values and Chi-squared test for ordinal values. Differences in personal characteristics were assessed using Chi-squared tests for categorical data and Student's t-tests for continuous data. Correlation among variables was assessed by single regression analysis. Because of the large number of correlations examined, a p-value of less than 0.01 was considered to be statistically significant. All analyses were performed using the Statistical Package for Social Sciences (SSPS).

Results

Tables 2 and 3 summarize the results of the SIP scores, and the lung function tests, respiratory and peripheral muscle strength assessments, respectively.

The total SIP scores for the patient group were significantly higher compared with the control subjects. In the patients with sarcoidosis, the subscores were significantly higher in the subscales "alertness behaviour", "home management", "recreation and pastimes", "sleep and rest", "social interaction" and "employment" (table 2).

Only one of the 18 patients had a slightly decreased TL,CO. The absolute values for FEV1 as well as FEV1 % pred were within the normal range for all patients, as also were the VC and TLC. However, FEV1 % pred was lower in the patients than in the control subjects.

HMF: hand muscle force; QF: quadriceps force; NS: non-significant. For further definitions see legend to table 3.

Muscle weakness is a condition in which the capacity for a rested muscle to generate force is decreased [23]. In our patient group, we found decreased \( P_{h, \text{max}} \) and \( P_{e, \text{max}} \), which indicates inspiratory as well as expiratory muscle weakness. Previously, reduced respiratory muscle strength in sarcoidosis was reported by Baydur et al. [13], who compared untreated patients suffering from sarcoidosis with control subjects, and found a decrease in maximal mouth pressures \( (P_{h, \text{max}}) \) in the sarcoidosis patients. In agreement with this, Badr and Sharma [14] found respiratory muscle dysfunction in 61% of a group of sarcoidosis patients. Moreover, in their study, the \( P_{e, \text{max}} \) was significantly lower than in normal controls [14].

The results of the present and previous studies, therefore, suggest that \( P_{h, \text{max}} \) and \( P_{e, \text{max}} \) are related to functional impairment due to sarcoidosis. These results also emphasize the need for an integrative approach in the assessment and therapeutic management of sarcoidosis. It should be noted, however, that the respiratory muscle tests applied in the present study depend on the cooperation of the patient. To the best of our knowledge, nonvolitional tests of respiratory muscle function, such as magnetic or electrical stimulation of the phrenic nerves, have not been reported in these patients.

Respiratory muscles are the major muscle groups used in supporting the ventilatory demands of exercise, and the effort required to drive the inspiratory muscles during exercise is a major contributor to the sensation of exertional dyspnoea [25]. With weak muscles, greater utilization of the available muscle mass is required to maintain a given external power output, resulting in an increased sense of effort. As a consequence, in persons with weak respiratory muscles, intolerable exertional discomfort and exertional dyspnoea occur at lower power outputs than in those with strong muscles [25]. In the present study, patients with symptoms had a decreased inspiratory muscle strength and endurance time, when compared to those without symptoms. The complaint of "fatigue" was associated with a lower expiratory muscle strength. Moreover, a relationship was found between the \( P_{h, \text{max}} \) and respiratory muscle endurance time. Thus, reduced respiratory muscle strength in the presence of sarcoidosis may contribute to exercise intolerance independent of impairment in ventilatory function. This conclusion is consistent with that of Hamilton et al. [25], who showed that in patients with cardiorespiratory disorders, respiratory, as well as peripheral, muscle strength was a significant contributor to symptom intensity and work capacity, in addition to any contribution from ventilatory, gas exchange, and circulatory impairment.

Several factors, such as hypoxaemia, hypercapnia, malnutrition, decreased blood supply to the muscles, drugs, and electrolyte abnormalities, contribute to respiratory muscle weakness and fatigue, e.g. in chronic obstructive pulmonary disease patients [26, 27]; however, these are unlikely to contribute in sarcoidosis. Which factor or combination of factors is responsible for this effect in sarcoidosis has not yet been established. In the absence of metabolic abnormalities, recent data have emphasized the role of inflammatory products on different aspects of muscle metabolism. As in other immunemediated disorders, most clinical manifestations of
sarcoidosis are secondary to the direct effect of the accumulation of activated immunocompetent cells in the involved tissues, notably helper T-lymphocytes and macrophages, and by an increased production of different cytokines [28, 29]. These cytokines appear to be produced in inflamed lesions of sarcoidosis and released into the bloodstream [30]. Future identification of these products could lead to specific therapeutic interventions aimed at blocking their effect in the clinical management of patients with inflammatory disorders, such as sarcoidosis.

As previously suggested, impaired respiratory muscle function suggests that the respiratory muscles can be involved in the granulomatous process of sarcoidosis [13]. Many reports have described granulomatous myopathy without overt manifestations of sarcoidosis elsewhere; sometimes a past history of sarcoidosis was suggested. Hence, granulomas in muscles may persist after those in other organs have become inactive or have resolved in patients who have passed through the active generalized stages of sarcoidosis without obvious symptoms [31]. Little is known about involvement of respiratory muscles, as only a few cases have been described [14, 32, 33]. For example, it is not known whether diaphragm and/or intercostal muscle involvement in sarcoidosis is a possible contributory factor to dyspnoea or impairment of vital capacity [31]. However, histological confirmation of respiratory muscle involvement is hard to obtain. Furthermore, myopathy, including disorders of the respiratory muscles, is a well-known side-effect of corticosteroids [34, 35]. It should be considered especially with higher doses of steroids, in the presence of markedly impaired respiratory muscle strength or continuous treatment with fluorinated steroids [36]. In the present group of patients, only seven had been treated with steroids during the 3 months prior to the study and the doses they received were low. Moreover, the respiratory and peripheral muscle strength did not differ between patients with or without a history of corticosteroid treatment.

The TLCO is considered by some authors to be the most sensitive index of lung function in sarcoidosis. It is often the first or only index to be decreased [14]. Remarkably, however, in the present study the respiratory muscle force and endurance were significantly lower than in the control group, even though other lung function tests were normal. This suggests that maximal mouth pressure and respiratory muscle endurance time may be more sensitive to functional impairment due to sarcoidosis than are the TLCO or VC, which have been suggested as the best indices to correlate with working capacity [37]. The relationship between radiographic stage, lung function and exercise abnormality have, however, been variable [38]. Clearly, there is a wide spectrum of tissue inflammation and organ dysfunction within, as well as between, each radiographic stage. KARETZKY and MCDONOUGH [38] found that the magnitude of functional impairment may vary widely from the apparent histopathological involvement as reflected by chest radiography and lung volumes. In the present study, we found a relationship between the radiographic stage and impairment in the fields "alertness behaviour", "emotional behaviour", "home management" and "social interaction".

Furthermore, in the present study, the SIP subscales "mobility" and "body care and movement" as well as the presence of symptoms were shown to correlate with respiratory muscle endurance time. However, for both of these latter domains there was no difference between patients and the control subjects. Moreover, our results show that patients with sarcoidosis are limited in physical and psychosocial functioning. They appear to be particularly affected in the fields "sleep and rest", "recreation and pastime", "employment", "alertness behaviour", "home management" and "social interaction", compared to a control group [15]. This diversity illustrates the broad impact of sarcoidosis on patients' quality of life.

In conclusion, respiratory muscle strength and endurance are reduced in patients with sarcoidosis. Decreased respiratory muscle endurance was found to be related particularly to the Sickness Impact Profile subscales "mobility" and "body care and movement". However, no such relationship was found between these latter Sickness Impact Profile subscales and routinely performed lung function tests, such as transfer factor and spirometry. Measuring respiratory muscle function seems to quantify and characterize the functional impairment in patients with sarcoidosis and reflects symptoms, such as fatigue and general weakness, that are otherwise difficult to assess objectively. Therefore, we suggest that measurements of respiratory muscle strength and endurance time could be usefully included in the diagnostic work-up and follow-up of patients with sarcoidosis. Further studies are needed to assess respiratory and peripheral muscle involvement, as well as the relationship with the presence of inflammatory characteristics in sarcoidosis.

Acknowledgements: The authors would like to thank H.M. Jacobs for providing the Dutch SIP control data, M.D.P. Elfferich and L.M.M. Kock for their great help in collecting the data and their advice. Furthermore, they would like to thank Ch. van der Grinten and G. Vissers for technical advice, J. de Vries for statistical assistance, and the lung function laboratory workers, in particular L. van de Pol, for technical assistance and advice.
