Abstract

We have introduced a single knock-out mutation in the mitochondrial creatine kinase gene (ScCKmit) in the mouse germ line via targeted mutagenesis in mouse embryonic stem (ES) cells. Surprisingly, ScCKmit—/— muscles, unlike muscles of mice with a deficiency of cytosolic M-type creatine kinase (M-CK—/—; Van Deursen et al. (1993) Cell 74, 621–631), display no altered morphology, performance or oxidative phosphorylation capacity. Also, the levels of high energy phosphate metabolites were essentially unaltered in ScCKmit mutants. Our results challenge some of the present concepts about the strict coupling between CKmit function and aerobic respiration.

Keywords: Creatine kinase; Mitochondria; Gene targeting; Energy homeostasis; Muscle physiology; Oxidative phosphorylation

1. Introduction

The flux of high energy phosphoryl groups between cellular sites of ATP production and utilization is controlled by the coupling of highly organized multienzyme systems which create an optimal microenvironment for efficient substrate and product channeling. Through such coupled systems high reaction rates can be achieved independently of the average concentration of high-energy metabolites (i.e., ATP) in the cytoplasm (Srere, 1987). This is especially important for tissues with large and sudden fluctuations in the use and synthesis of ATP, such as nerve and muscle. One of the cellular systems involved in maintenance of the proper energy balance comprises the family of creatine kinase isoenzymes (CKs), which catalyse the reversible exchange of high-energy phosphate between ATP and phosphocreatine (PCr): MgADP2— + PCr2— + H+ ↔ MgATP2— + Cr (Fig. 1, Bessmann and Carpenter, 1985; Wallimann et al., 1992). In birds and mammals, five CK isoenzymes have been identified which are expressed tissue-specifically, and vary with regard to their intracellular (sub)localization. Three of the five CKs are cytosolic enzymes which exist as dimers composed of the M (for muscle) and B (for brain) subunits (Fig. 1). They assemble into the homodimeric CKMM and CKBB, or heterodimeric CKMB isoenzymes, with molecular masses varying from 80 to 86 kDa. CKMM is predominantly found in mature skeletal and cardiac muscle. CKBB activity is highest in brain and neural tissue, embryonic cardiac and skeletal muscle, and in a large array of cells with very specialized functions such as photoreceptor cells of the retina, spermatooza, smooth muscle cells, placenta, and epithelial cells of uterus, kidney and intestine (Wallimann et al., 1992; Ikeda, 1988; Friedman and Perryman, 1991; Ishida et al., 1994). The CKMB isoform is mainly found during embryonic development of striated muscle when a
Fig. 1. The CK/PCr system in cellular energy metabolism (A) and genes and proteins of the CK isoenzyme family (B). (A) The CK/PCr system and its relation to pathways for energy supply are represented schematically. The major cellular compartments involved in the energy metabolism are drawn within dashed lines. The boxes depicted in the cytoplasm represent the freely exchangeable pools of PCr, Cr, ATP and ADP in this compartment. The size of the individual pools is very much dependent on the tissue and cell type. ATPases may represent the myofibrillar actin-activated Mg\textsuperscript{2+}-ATPase, the plasma membrane or sarcoplasmic reticulum Ca\textsuperscript{2+}-ATPases, or Na\textsuperscript{+}/K\textsuperscript{+}-ATPases. The adenylate kinase (AK) system which provides a parallel and partially overlapping system for high energy phosphoryl exchange reactions is not shown here. (B) Four functional nuclear genes encode the individual CK subunits. Exons of the genes (drawn on scale) are depicted as boxes; lengths of introns (which vary considerably and are much larger in the M-CK and ScCKmit genes than in the B-CK and UbCKmit genes) have not been considered and are therefore not given according to scale. Untranslated regions are blank, coding sequences of all genes are in solid grey, and the regions of the CKmit genes encoding the mitochondrial targeting sequences are dotted. Asterisks mark the only exon that is shared between all CK genes. In the translated CK peptide shown, six blocks (I–VI) constitute the CK framework, while 9 domains (A–I) are specific for cytosolic or mitochondrial CKs, or for one of the four subtypes. The first block at the N-terminus is the mitochondrial targeting peptide which is proteolytically removed after mitochondrial import. Finally, the individual subunits assemble into enzymatically active proteins in the cytosolic and mitochondrial compartments. Data from Mühlebach et al. (1994) served as basis for this figure.
mitochondrial intermembrane space: the ubiquitous distinct subtypes which are specifically located in the mammalian heart. The remaining two CK isoforms are expressed in those cells and tissues where B-CK is active; typically, the ScCKmit is expressed in striated muscle tissue, (Jacobus and Lehninger, 1973; Hossle et al., 1988). Typically, the ScCKmit is expressed in those cells and tissues where B-CK is active (Wallimann et al., 1992; Wyss et al., 1992). Upon entry in mitochondria their N-terminal import signal is removed and the mature CKmit subunits assemble into stable 75-89 kDa dimeric and 317-377 kDa octameric molecules (Mühlebach et al., 1994; Hossle et al., 1988; Haas et al., 1989; Payne et al., 1991). Here they concentrate at contact sites where the outer and inner membranes are in close apposition (Adams et al., 1989). It is likely that the dynamics of mitCK octamer/dimer formation and the association to these sites in vivo (Knoll and Brdiczka, 1990; Rojo et al., 1991) are influenced in response to varying energy demands and are important physiological mechanisms for regulating the enzyme’s catalytic properties, the high-energy phosphoryl flux into the cytosol (Veksler and Ventura-Clapier, 1994; Saks et al., 1994), and the OXPHOS and glycolytic activity of cells (Erecinska and Wilson, 1982; Balaban, 1990; Scopes, 1973). In these reaction cascades the ADP ⇔ ATP + AMP exchange mediated by adenylate kinases may also be involved (Gellerich, 1992; Savabi, 1994). Furthermore, in the cytoplasmic space, CKs assist in the compartmentalization of ATP and ADP (Jones, 1986; Miller and Horowitz, 1986). In muscle, CKMM mediated ATP production is coupled to the local activity of SR- and plasma-bound Ca²⁺-ATPases (Levitsky et al., 1978; Rossi et al., 1990; Korge and Campbell, 1994), the Na⁺/K⁺-ATPase (Saks et al., 1977; Grosse et al., 1980) and the myosin ATPase involved in actin-myosin sliding during contraction (Wegmann et al., 1992; Turner et al., 1973; Saks et al., 1976; Ventura-Clapier et al., 1987, 1994. Likewise, the coupling to CKBB may be of functional importance for the action of Na⁺/K⁺-ATPase in specialized cell types with the brain, kidney and many other tissues (Hemmer and Wallimann, 1993; Friedman and Roberts, 1994). Furthermore, there are suggestions that the CK/PCr system (via B-CK) may play a role in neurotransmitter release, the maintenance of membrane potentials, restoration of ionic gradients in neurons, spatial K⁺ buffering in Bergmann glial cells, metabolic interactions between astrocytes and neurons, myelin synthesis by oligodendrocytes, and restoring K⁺ ion gradients in glomerular structures in the cerebellum (Friedhof and Lerner, 1977; Lim et al., 1989; Blum et al., 1991; Reichenbach, 1991; Hemmer and Wallimann, 1993; Hemmer et al., 1994).

In order to obtain a better understanding of the subcellular partitioning of components of the CK/PCr system, and to unravel its role in the compartmentalization of energy homeostasis in different cell types, it will become of utmost importance to apply experimental methods which preserve the integrity of the cells delicate organization, and the communication between specific cellular ‘aggregulons’ or microcompartments. Fortunately, the rapid development of techniques to manipulate gene expression in vivo, in cells and experimental animals, is providing us with powerful new tools for these kind of studies. Normal or mutant genes of interest can be either overexpressed, or their expression can be directed to specific tissues using ‘conventional’ transgenesis by micro-injecting DNA into the fertilized egg (Jaenisch, 1988). In an alternative approach, gene targeting in mouse embryonic stem (ES) cells creates the possibility to produce mice carrying predesigned mutations in the germline (Thomas and Capecchi, 1987). This sophisticated technique, mostly applied as a gene ‘knock-out’ mutagenesis method, has already been used to generate over 400 new mouse lines (Brandon et al., 1995) and is currently one of the methods of choice for revealing unknown gene functions, and for understanding gene functions in the context of the whole animal (see Capecchi, 1989; Evans, 1989; Joyner, 1991; Rossant, 1991; Smithies, 1993 for review). We and others have applied the methodology for altering the expression levels of the different CK isoenzymes in vivo. Transgenic techniques have been applied to direct B-CK and UbCKmit isoenzyme expression to mouse liver, as well as to induce ectopic B-CK expression in striated muscle tissue (Koretsky et al., 1990; Brossnan et al., 1990, 1993). Our group has generated mice completely deficient in M-CK subunits and mice expressing reduced levels of M-CK by gene targeting. The biological consequences of these mutations have been characterised (Van Deursen et al., 1993, 1994a,b). Likewise, animals with a deficiency in the ubiquitous mitochondrial CK subform (UbCKmit), with surprisingly little phenotypic effects, have been generated (Steeghs et al., 1995a,b). Here, as an illustration of the potential usefulness of the methodology, we address specifically the role of the sarcomeric mitochondrial CK (ScCKmit) reaction and report on the biochemical, physiological and morphological consequences of knock-out of the ScCKmit gene. As the effects are unexpectedly milder, some of the simplified concepts for the role of the CK system in energy delivery to muscle may need revision, and are challenged in the discussion.

2. Experimental procedures

2.1. Construction of the targeting vector

An EMBL3 phage library of partially digested genomic DNA of the 129/Sv mouse strain (D’Azzo and Grosveld,
A wild-type allele

B targeting vector

C targeted allele

D

E

F

G

anti ScCKm1t

anti UbCKm1t
unpublished) was screened using a 2.1 kb fragment containing the complete mouse ScCKmit cDNA. Eight positive phages were purified to homogeneity and a common 7 kb PstI fragment comprising amino acid positions 1–185 of the mature protein (including the 39 N-terminal residues of the mitochondrial transit peptide) was subcloned into plasmid pGEM3 (Promega). To construct a replacement type of targeting vector, a 0.4 kb SsrI-SmaI fragment, encompassing parts of intron 2 and exon 3 and including the ATG translation start codon, was deleted from this genomic clone and replaced by a 2.0 kb blunt-ended cassette carrying the hygromycinB resistance (hygroB') gene (Van Deursen et al., 1992). A cassette containing a 2.0 kb herpes simplex virus thymidine kinase gene (Van Deursen et al., 1992). A cassette containing a 2.0 kb herpes simplex virus thymidine kinase gene (Van Deursen et al., 1992) was introduced in the upstream site (Fig. 3). The targeting vector was linearized at the most 3' located BamHI site prior to ES cell electroporation.

2.2. ES cell culture, transfection, and selection

Wild-type E14 ES cells (kindly provided by Dr. Plump, Rockefeller University, New York, NY) were cultured on a layer of irradiated (3000 rad) SNLH9 feeder cells (Van Deursen et al., 1992) and electroporated essentially as described (Steeghs et al., 1995a,b). ES cells were resuspended in culture medium (at 1.8 x 10⁷ cells/ml in 0.8 ml) mixed with 20 μg of BamHI-linearized DNA and electroporated at 500 μF and 250 V (Bio-Rad Gene Pulser) before plating on two 10-cm dishes containing irradiated feeder cells. Positive-negative selection was applied for 8–10 days, starting 24 h after electroporation, with 300 μg/ml hygromycinB (ICN Biomedicals, Aurora, Ohio) and 0.2 mM FIAU (1-[2'-deoxy-2'-fluoro-β-D-arabinofuranosyl]-5-iodouridine, kindly provided by Bristol-Meyers).

2.3. Generation of ScCKmit deficient mice

Expanded E14 clones showing genuine recombination events were cytogenetically typed and ultimately 8–12 cells from six independent clones were injected into recipient C57BL/6 blastocysts, and implanted into the uterine horns of pseudopregnant foster mothers (Bradley, 1987). The resulting chimaeric males were mated with C57BL/6 females to score for germline transmission of the mutation and offspring heterozygous for the mutant ScCKmit allele were identified by Southern blot analysis. Genotypes of pups resulting from crosses between heterozygotes were PCR analyzed and ScCKmit null mutants (ScCKmit−/−) from one ES cell line were selected for further breeding.

2.4. Genomic DNA analysis

Genomic DNA from ES cells or mouse tail biopsies was isolated and used for Southern blot analysis following standard procedures as described (Steeghs et al., 1995b). Probes to identify targeting events were a 500 bp HaeIII-Apal fragment at the 5' side and a 300 bp BamHI-PstI fragment at the 3' side (see Fig. 2). PCR was used for genotyping offspring using three primers in one reaction mixture. Forward primers were Sc1 located in exon 3 (5'-AAGAGGAAAGATGCGCAGTCG-3') and H1 located in the hygroB' gene (5'-GGCTG-GCACTCTGTCAATCCC-3'). Sc2 is the reverse primer located in intron 3 (5'-AATTCGAGCCTCACCAG-GCA-3') of the ScCKmit gene. Following an initial denaturation step (96°C for 1 min) 30 consecutive cycles of PCR, in 50-μl volumes containing 10 mM Tris-HCl pH 8.3, 50 mM KCl, 1.5 mM MgCl2, 0.01% gelatin, 100 ng of each primer, 100 ng DNA template and 1 U Ampli-Taq™ DNA polymerase (Perkin Elmer Cetus), were per-
formed (94°C for 1 min, 60°C for 1 min and 72°C for 2 min). The product diagnostic for the wild-type locus is 424 bp; the mutant allele product has a length of 702 bp.

2.5. Northern blot analysis

Total RNAs from freshly removed skeletal muscle, heart, and brain were extracted using the lithium chloride-urea method and analyzed by Northern blot analysis as described (Steeghs et al., 1995b). RNA blots were hybridized with 32P-labeled probes of: (i) the genomic 0.4 kb SstI-SmaI fragment that was deleted in the targeting vector; (ii) a fragment of the ScCKmit cDNA covering parts of exons 3 and 4 (bp 50–230 of the cDNA, translation start at +1); (iii) a 150 bp fragment specific for the 5' untranslated region of the mouse ubiquitous CKmit gene (Steeghs et al., 1995b); and (iv) a 1.3 kb PstI glyceraldehyde-3-phosphate dehydrogenase (GAPDH) cDNA probe of rat.

2.6. Immunoblot analysis

For Western blot analysis, freshly frozen tissues of total brain, heart muscle and total hind leg muscle were homogenized at 4°C with a teflon-glass Potter-Elvehjem homogenizer in 10 volumes SETH buffer (250 mM sucrose, 2 mM EDTA, 10 mM Tris-HCl at pH 7.4, and 50 U/ml heparin). Approx. 40 μg total extract protein was separated on a 10% (w/v) SDS-polyacrylamide gel, transferred onto nitrocellulose membrane and processed as previously described (Steeghs et al., 1995a). CKmit protein was detected with subunit-specific polyclonal antibodies raised against synthetic peptides of the ScCKmit or UbCKmit isoforms (Friedman and Perryman, 1991). The ScCKmit specific antibody was used at a 1:10000 dilution. Visualization of signal was by horseradish peroxidase-conjugated goat-anti-rabbit secondary immunoglobulin G (Amersham Life Sciences) was used at a dilution of 1:5000 in TBST, and the immunodetection with 1:300 diluted αUbCKmit antibody was performed as described (Steeghs et al., 1995b). RNA blots were hybridized with 32P-labeled probes of: (i) the genomic 0.4 kb SstI-SmaI fragment that was deleted in the targeting vector; (ii) a fragment of the ScCKmit cDNA covering parts of exons 3 and 4 (bp 50–230 of the cDNA, translation start at +1); (iii) a 150 bp fragment specific for the 5' untranslated region of the mouse ubiquitous CKmit gene (Steeghs et al., 1995b); and (iv) a 1.3 kb PstI glyceraldehyde-3-phosphate dehydrogenase (GAPDH) cDNA probe of rat.

2.7. CK isoenzyme activity analysis of tissue extracts

Extracts for zymogram analysis were prepared and assayed as described (Steeghs et al., 1995a,b).

2.8. Measurement of mitochondrial enzyme activities

600 × g supernatants of homogenates from freshly excised heart (5% w/v) and total hind leg muscles (20% w/v) were prepared in SETH buffer at 4°C. Crude mitochondrial suspensions were prepared by centrifugation at 14000 × g, washing the mitochondrial pellet once with SETH-buffer, and suspending the mitochondria in a volume of SETH-buffer corresponding to their volume in the 600 × g supernatant. Cytochrome c oxidase and citrate synthase activities were determined according to the methods of Cooperstein and Lazarow (1951) and Srere (1969), respectively. [1-14C]Pyruvate oxidation rates were measured in the presence of malate, with and without ADP (Fischer et al., 1986). ATP and P Cr production from arsenite sensitive pyruvate oxidation was assayed by coupled enzyme reactions, monitoring the increase in NADPH at 25°C and 340 nm (Fischer et al., 1986).

2.9. Chemical analysis of metabolite concentrations

For analysis of metabolite concentrations, female mice were anaesthetized with pentobarbitone (90 mg/kg body-mass; i.p.). Medial gastrocnemius muscles were exposed, immediately clamp frozen in brass tongs precooled with liquid nitrogen, pulverized in a mortar under cooling with liquid nitrogen, and freeze-dried overnight. Metabolites were extracted from portions of ± 80 μg dry tissue powder in 60% (v/v) methanol at —80°C for at least 24 h. Metabolites were separated isocratically with high performance liquid chromatography (HPLC) using RP-18 columns (Hewlett Packard). The eluents for separation of nucleotides consisted of 215 mM phosphate buffer (pH 6.5), 2.3 mM t-butylammonium hydroxysulphate (TBAHS) and 2% acetonitrile (Sellevold et al., 1986). PCr and Cr were separated with a mixture of 14.7 mM phosphate buffer (pH 6.5) and 2.3 mM TBAHS (Dunnett et al., 1991). For quantification of the metabolites a UV detector was used with a wavelength of 254 nm for the nucleotides and 210 nm for PCr and Cr. Glycogen levels were assayed as described (Van Deursen et al., 1993).

2.10. Histochemistry

Routine histological and histochemical analysis of muscle sections was performed as described (Van Deursen et al., 1993). For analysis of myosin heavy chain (MHC) composition, several muscles from a wild-type and ScCKmit−/− mutant females were isolated. MHC isoforms were separated from crude myosin extracts by gradient polyacrylamide gel electrophoresis and silver-stained gels were evaluated densitometrically, essentially as described by Hämäläinen and Pette (1993).

2.11. 31P-NMR spectroscopy

For in vivo 31P-NMR spectroscopic analysis, mice were anaesthetized with 1–2% enflurane in 30% O2/70% N2O delivered through a face mask. During experimentation the rectal temperature was monitored and maintained at 36.5°C.
3. Results

3.1. Targeted disruption of the ScCKmit locus

For disruption of the ScCKmit gene, a targeting vector as shown in Fig. 2B was used. This targeting construct was designed to replace a 400 bp genomic fragment encoding the mitochondrial transit peptide and the first three amino acids of the mature protein with a hygroB gene. We deliberately chose for removal of this segment to prevent the (hypothetical) formation of truncated protein products with signals for import into mitochondria, thus avoiding undesired dominant-negative effects. After transfection of E14 embryonic stem cells with the linearized targeting vector a total of 35 clones (19% of clones selected) harbouring the desired mutation were identified. Diagnostic Southern blotting with 5′ and 3′ external probes showed the predicted 10.4 and 8.5 plus 4 kbp EcoRI fragments associated with the wild-type and mutant alleles, respectively, indicating that correct homologous recombination events had indeed occurred at both sides of the disruption in all clones (Fig. 2D).

3.2. Generation and characterisation of mutant mice

Six targeted clones were used to generate male chimaeras and germline transmission was achieved for two clones. The highest transmitting line was chosen for heterozygous intercrossings to obtain mice with disruptions of both ScCKmit alleles. Litter sizes were normal and genotyping of offspring by PCR analysis (Fig. 2E) showed the expected Mendelian distribution of wild-type mice and heterozygotes and null mutants, ScCKmit[−/−] mutant mice appeared healthy and displayed no gross abnormalities, behavioral defects or impaired reproductivity. To verify that the gene disruption had indeed created a null mutation, the expression of ScCKmit in skeletal and cardiac muscle was examined. Northern blot hybridization with the deleted 400 bp fragment, covering part of exon three, showed no 1.6 kb ScCKmit mRNA product in homozygous mutant mice, while levels in the heterozygotes were approximately half of those expressed in wild types (Fig. 2F). However, a ScCKmit cDNA probe spanning parts of exons 3–4 hybridized to a smaller sized (1.5 kb) mRNA product. Since a similar product was seen by a ScCKmit cDNA probe spanning exons 6–8 (not shown) we surmise that this mRNA product is derived from the aberrant splicing of mutant transcripts that initiate somewhere in the hygroB gene, but the exact nature of this remnant mRNA was not investigated further. Hybridization of the RNA blot with a cDNA probe specific for the 5′UTR in mRNA for mouse ubiquitous CKmit (UbCKmit, see for details Steeghs et al., 1995b) detected no UbCKmit mRNA transcripts in total RNA preparations of ScCKmit deficient cardiac or skeletal muscle (Fig. 2F). This suggests that expression of the other mitochondrial CK isoform is not upregulated to detectable levels to compensate for ScCKmit deficiency.

The levels of expression of ScCKmit protein subunits were examined by Western-blot analysis, using a rabbit polyclonal anti-ScCKmit antiserum that was raised against a conserved peptide comprising amino acids 98–114 of the mature polypeptide (Friedman and Perryman, 1991). This
protein segment is encoded by parts of exons 5 and 6, and is thus located carboxy-terminal from the region that was deleted by homologous recombination. As anticipated, no protein was detectable in cardiac and skeletal muscle lysates from homozygous mutant animals (Fig. 1G) indicating that the residual mRNA transcript cannot encode any stable protein product. When the blots were subsequently incubated with a polyclonal antibody raised against a short unique peptide in the UbCKmit isoform subunit (Friedman and Perryman, 1991) approximately equally weak signal intensities were seen in both muscle tissues in wild-type, heterozygous, and ScCKmit[−/−] mice (Fig. 2G) confirming the findings with Northern blot analysis.

CK activities in heart and skeletal muscle extracts were determined biochemically and found to represent approx. 60 and 95%, respectively, of activities in wild-type muscles. These values are mainly attributable to the presence of M-CK isoenzyme in sarcoplasm, and include the low levels of B-CK and UbCKmit isoenzymes which originate from vascular smooth muscle or satellite cells in skeletal muscles (Payne et al., 1991).

3.3. Is there a role for ScCKmit in control of respiratory rate and levels of high energy phosphoryl metabolites?

Regulation of OXPHOS activity and oxygen consumption in muscle cells is controlled by complex interactions among metabolic pathways in which Cr levels and CKmit activity may be important parameters (Wyss et al., 1992). However, as shown in Table 1, specific activities of two mitochondrial marker enzymes, cytochrome c oxidase (COX) and citrate synthase (CS), were essentially similar in wild-type and ScCKmit[−/−] heart and hind limb muscles. Furthermore, neither the mitochondrial capacity to oxidize pyruvate in the presence of malate, the resulting high-energy phosphoryl production (measured as the 14CO2 derived from oxidation of [1-14C]pyruvate, and the arsenite-sensitive mitochondrial generation of ATP + PCr, respectively), nor the ADP stimulation rates in supernatants or isolated mitochondria were compromised by the ScCKmit knock-out mutation. One of the postulated functions of soluble CKs is to keep the cellular ATP pool highly charged and to prevent large fluctuations in the overall ATP/ADP ratio. Therefore, chemical methods were used to examine whether ScCKmit or total CK deficiency had influenced the levels of energy related metabolites in muscles at rest (Table 2). Levels of all metabolites in ScCKmit[−/−] muscles were similar to wild-type values.

3.4. Changes in profiles of contractile proteins

We considered the possibility that CK mutations would bring about an altered response to workload in muscle. As alterations in myosin heavy chain isotype (MHC) distribution are often indicative for activity changes or for regenerative processes (Pette and Vrbová, 1992; Sweeney et al., 1988) MHC typing was performed by gradient gel electrophoresis of muscle extracts under denaturing conditions. Comparison of the distribution patterns in the representative slow soleus muscle, the intermediate type gastrocnemius (Fig. 3A) and diaphragm muscle, and the fast psoas and extensor digitorum longus (EDL; Fig. 3B) muscle, showed that transitions in isomyosin heavy chain types do not occur in either of these types of muscle in ScCKmit[−/−] mice.

| Table 1 |
| --- | --- |
| Activities of mitochondrial enzymes and oxidative phosphorylation characteristics in hind limb and cardiac muscle of wild-type and ScCKmit[−/−] mice |
| 600 g supernatant | Isolated mitochondria |
| Muscle | 353 ± 76 (9) | 320 ± 64 (11) | 5570 ± 1388 (6) | 5306 ± 2251 (5) |
| Heart | 955 ± 303 (13) | 1127 ± 424 (13) | 9324 ± 3564 (6) | 9145 ± 2655 (6) |
| CS activity | 69 ± 15 (9) | 63 ± 12 (11) | 861 ± 274 (6) | 902 ± 383 (5) |
| Muscle | 236 ± 57 (13) | 263 ± 72 (13) | 1007 ± 161 (6) | 1132 ± 150 (6) |
| Heart | 1.97 ± 1.02 (8) | 1.41 ± 0.63 (10) | 0.77 ± 0.27 (5) | 0.60 ± 0.21 (4) |
| 14CO2 production | 2.13 ± 1.14 (11) | 1.39 ± 0.59 (10) | 2.47 ± 0.50 (6) | 1.79 ± 0.75 (5) |
| Muscle | 26.3 ± 7.1 (11) | 27.1 ± 8.5 (8) | 30.7 ± 3.2 (4) | 23.7 ± 4.4 (4) |
| Heart | 14.3 ± 4.7 (8) | 15.2 ± 4.9 (8) | 17.9 ± 3.5 (4) | 12.1 ± 3.7 (3) |
| ATP + PCr production | 3.1 ± 0.8 (8) | 3.5 ± 1.3 (5) | 4.5 ± 0.7 (5) | 5.4 ± 1.3 (5) |
| Muscle | 3.5 ± 1.0 (10) | 3.3 ± 0.8 (10) | 4.0 ± 0.6 (5) | 2.7 ± 0.3 (4) |

Values are means ± SD (number of experiments). N.D., not determined. Activities of cytochrome c oxidase (COX) and citrate synthase (CS) are in µM/mg protein; 14CO2 and ATP + PCr production is expressed in µmol/h per U CS. ADP stimulation expresses the difference in 14CO2 production with and without addition of ADP.
3.5. Characterization of skeletal muscle of CK mutant mice by $^{31}$P-NMR spectroscopy

Since the phosphorylated metabolites directly measured by in vivo $^{31}$P-NMR are intimately related to the CK/PCr system, this technique is most suitable to study the role of CK enzymes in energy conversion processes in intact resting and working muscle. Therefore, in vivo $^{31}$P-NMR spectroscopy of intact hindlimb muscle of anaesthetized ScCKmit[−/−] and CK[−/−] mice at rest was performed. To determine the relative levels of NMR-visible energy metabolites at rest, fully relaxed $^{31}$P-NMR spectra were acquired. Relative peak areas of energy metabolites in wild-type and ScCKmit[−/−] single mutants in the spectra from hindlimb muscles showed no differences (Table 2, Fig. 4). Also, flux studies (see Van Deursen et al., 1993) revealed no abnormalities as the forward ($K_r$) and reverse ($K_r$) pseudo-first order rate constants for the high-energy phosphate transfers between ATP and PCr were $0.39 \pm 0.08$ and $1.19 \pm 0.28 \text{ s}^{-1}$, respectively ($n = 4$) for ScCKmit[−/−] muscle, similar to the values of rate constants in wild-type muscle (Van Deursen et al., 1993). Finally, pH calculations yield similar values for wild-type ($7.29 \pm 0.07$) and ScCKmit mutants muscles ($7.17 \pm 0.05$).

The concentrations of various energy metabolites were either determined by chemical analysis of snap-frozen medial gastrocnemius muscle or calculated from the relative peak areas (fraction of total integral) of phosphate metabolites in fully relaxed NMR spectra of whole hind limb skeletal muscle of wild-type and CK-mutant mice. Values from chemical quantitation are mean ± SD, indicated in μmol per g dry weight. In order to diminish variations mainly caused by the variable presence of non-muscle constituents in the dry tissue powder, Cr and PCr concentrations were normalized for the mean total Cr±PCr content of all muscles. NMR spectral values are calculated as mean ± SD, indicated in % of the total integral. Mean ATP is the average of the three ATP resonance peaks. Ratios calculated from the chemical determination and NMR measurements are given individually. The numbers of experiments when the phosphomonoester (PME) signal was clearly above the noise level are given within parentheses. The total number of determinations was $n = 6$ for wild-type and CK[−/−], $n = 5$ for M-CK[−/−] animals, and $n = 4$ or $n = 6$ for chemical determination, or NMR determination of ScCKmit[−/−] animals, respectively.

Surprisingly, the flux of reversible high energy phosphoryl transfer between PCr and ATP in 1 and 5 Hz stimulated muscle was also apparently normal (data not shown).

3.6. ScCKmit[−/−] muscles have normal force and relaxation characteristics

To test whether the defects in the CK/PCr system would influence the excitation-contraction process, muscles of wild-type and ScCKmit mutant mice were subjected to high-intensity exercise protocols to study force generation under conditions of high metabolic flux. In all experiments, contractile performances of ScCKmit[−/−] muscles were similar to those of wild-type muscles. There was no difference in maximal twitch force between the four groups of mice, or in the time-to-peak or half-relaxation times of the twitch contractions (Table 3).

3.7. Light microscopical and ultrastructural analyses of abnormalities in ck[−/−] muscles

Cross-sections from various muscles were stained with hematoxylin/eosin, and assayed histochemically for ATPase pH 4.3 and succinate dehydrogenase activity. Both the general appearance of stainings, as well as the sizes and fiber-type distributions were similar in mutant and wild-type mice (Fig. 5). Also at the ultrastructural level, the EM analysis of sections of diaphragm, heart, intercostal, gastrocnemius and soleus muscles of 7-14-week-old ScCKmit[−/−] mice revealed no distinct morphological abnormalities in either the myofibrillar compartment or the mitochondrial ultrastructure, i.e., the arrangement of outer and inner mitochondrial membranes and cristae. This is in marked contrast to the finding of enlarged intermyofibrillar mitochondrial volume that was apparent in type 2 (fast) fibers of M-CK deficient GPS muscles (Van Deursen et al., 1993) upon light- and electron-microscopical analyses.

4. Discussion and conclusions

4.1. Mitochondrial creatine kinase deficiency has no overt phenotypic consequences

The complete absence of biochemical, physiological and ultrastructural consequences of single gene knock-out in our ScCKmit mutant animals is indeed surprising and suggests that escape routes in the elaborate energy transmitting kinase network at the mitochondrial surface may help in masking the loss of ScCKmit activity. Strikingly, no compensatory increase in the levels of mitochondrial marker enzymes, as often seen in human mitochondrial myopathies (Brown and Wallace, 1994), or any significant alterations in the phosphorylation index were observed. Obviously, ATP synthesized by mitochondria can (and most likely also does) reach the cytoplasmic compartment.
independently of the ScCKmit reaction. Whether in this situation the full rate of PCr production proceeds via the catalytic conversion by cytosolic MMCK, or whether a specific relocation of MMCK to sites in the immediate vicinity of mitochondria ameliorates the effects, remains a subject for further study. NMR studies did shed some light on this issue. Standard spin inversion transfer experiments indicate no abnormality for PCr ↔ ATP exchange in hind leg muscle of ScCKmit[−/−] mice. In contrast, preliminary data of saturation transfer on isolated ScCKmit[−/−] hearts in Langendorff perfusion did show a significantly reduced transfer (K. Nicolay, personal communication). These differential findings may either directly reflect the differences in ScCKmit content (see Fig. 2F,G), or point to the existence of a pool of ATP at the mitochondrial compartment with properties requiring a different NMR magnetization transfer technique for their detection in these tissues (Zahler et al., 1987).

Likewise, in our studies of twitch force, tetanic force, force during repeated isometric contractions, or half relaxation times we may have missed specific physiological manifestations because more adequate protocols must be designed to challenge the enzymatic network involved in aerobic long-term muscle performance sufficiently. The possibility thus remains that a critical low threshold in oxidative energy production may only be reached at more advanced ages when the usual progressive decrease in mitochondrial electron transport capacity would add to the CKmit deficiency. Yet, based on our data thus far with animals of over 18 months of age, it is fair to conclude that ScCKmit activity is not obligatory for regulation of OXPHOS flux or phosphoryl exchange rates, which in turn determine the contractile properties of muscle tissue.

Our findings are surprising in view of the proposed crucial role of CKmit in the high energy phosphate throughput in the mitochondrial intermembrane space (see Section 1 and Wallimann et al., 1992 for reviews). There is, however, the possibility that ‘rewiring’ of metabolic pathways at or even within the microcompartments or multienzyme complexes of the mitochondria can take over the role of the ablated CKmit. Mitochondrial adenylate kinase (AKmit or AK2), is a strong candidate as it permanently equilibrates the adenine nucleotides at this location. In the absence of creatine, ADP is also preferentially used for oxidative phosphorylation and only partially accessible to extramitochondrial circuits. The AKmit mediated stimulus of oxidative phosphorylation is comparable to, or even higher than, the CKmit mediated increase (Gellerich, 1992; Gellerich et al., 1994). It is therefore tempting to speculate that both shuttles contribute to the ATP/ADP conversions at the mitochondrial site (Savabi, 1994). Bessmann and Carpenter (1985) suggested the existence of a tetrahedral arrangement of one molecule of CKmit with two molecules of AKmit clustered around the ANT. Indeed, direct transfer of the β-phosphate of ATP to creatine (Yang et al., 1977) indicates a close association between these enzymes (see also Zeleznikar et al., 1995).

In summary, our results show that muscular function is not absolutely dependent on presence of CKmit. Although we have not challenged the energy system under extreme conditions such as anoxia (Miller, 1993) or high-work performance we surmise that – as in many other KO mutant mouse models – the mild phenotype may result from spreading or dilution effects (i.e., flux redirection) in a complex cellular network. There are many reasons to believe that energy homeostasis is such a complex network and therefore further ablation of genes for essential components other than CKs will be necessary to unveil the distinct biochemical and physiological functions of the CK/PCr system in the mitochondrial compartment.
