Recent case-referent studies in the Nijmegen breast-screening programme have shown a reduction in breast-cancer mortality of approximately 50% due to screening of women aged 65 years and older. In this type of study, however, the results may be biased because of self-selection. The purpose of our present study was to compare the breast-cancer mortality rate in a population invited for screening with that of a reference population from an area without a screening programme. In 1977-1978, 6773 women aged 65–74 years were enrolled in the mammographic screening programme in Nijmegen, The Netherlands. The women were followed up until 31 December, 1990. The reference population consisted of women from the same birth cohort from Arnhem, a neighbouring city without mass screening, for whom the entry date was 1 January, 1978. The ratios of the Nijmegen and Arnhem breast-cancer mortality rates with 95% confidence intervals (CI) were calculated. In the study period, 173 patients were diagnosed with primary breast cancer in Nijmegen vs. 183 in Arnhem; 40 Nijmegen patients had died of breast cancer vs. 51 Arnhem patients. The cumulative mortality-rate ratio was 0.80 (95% CI = 0.53–1.22). In the periods 1978–1981, 1982–1985 and 1986–1990, the mortality rate ratios were 1.44 (95% CI = 0.67–3.10), 0.81 (95% CI = 0.37–1.79) and 0.53 (95% CI = 0.27–1.04), respectively. After adjustment for the difference in incidence rate expected to yield a 40% reduction in breast-cancer mortality after 10 years. Int. J. Cancer, 70:164–168, 1997.

Unlike most malignancies, the course of breast cancer can be altered by early detection and treatment. In women over the age of 50 years, trials have shown a reduction of breast-cancer mortality of some 25 to 30% in populations that were offered screening vs. unscreened populations (Fletcher et al., 1993; Nystrom et al., 1993; De Koning et al., 1995; Kerlikowske et al., 1995). The screening intervals used in these studies ranged from 12 to 33 months and the screening test consisted of 1- or 2-view mammography, sometimes in combination with physical examination.

More recently, a reduction in mortality has been demonstrated in women up to the age of 75 years (Van Dijck et al., 1994, 1996; Chen et al., 1995). The results of the Swedish 2-county study, which was a randomized trial, showed a decrease in breast-cancer mortality due to the screening of women aged 65 to 74 years at entry (Chen et al., 1995). After 14 years of follow-up, a statistically significant 32% reduction in the risk of death from breast cancer was observed in the population invited for screening. In Nijmegen, 2 case-referent studies included women aged 65 years and older at the index invitation (i.e., the most recent invitation to screening just prior to the diagnosis of breast cancer in the case). The estimated reductions in breast-cancer mortality in women screened at the index invitation relative to those unscreened at that time were 42% and 44% after 13 and 18 years of follow-up respectively (Van Dijck et al., 1994, 1996). There has been debate, however, on the validity of case-referent studies as a method of evaluating screening efficacy, since the results may be biased due to self-selection for screening (Morrison, 1993; Moss et al., 1992). The present study used an external reference population to evaluate whether including elderly women in a screening programme affects breast-cancer mortality.

SUBJECTS AND METHODS

In 1975, a breast-cancer screening programme was started in the city of Nijmegen, The Netherlands (Otten et al., 1996). Initially, women born between 1910 and 1939 (aged 35–66 years) were invited for one-view mammography. Since the second round of screening, 1977–1978, women born before 1910, aged 67 years and older at their first invitation, have also been invited biennially to participate in the screening. The present study included all Nijmegen women born between 1895 and 1909 who had been invited to screening before the end of 1990. In this way, 6773 women entered the screening programme in round 2, while 488 women, who had come to live in Nijmegen after round 2, joined the programme between 1979 and 1990.

Information about invitation and participation of the invited women was stored in a computer file. With the aid of the local authorities, follow-up could be recorded. All patients diagnosed with breast cancer (screen-detected and clinically diagnosed) at either of the 2 Nijmegen hospitals were registered at the Department of Radiology of the University Hospital. Clinical information about deceased patients was obtained from their medical files and reviewed by a panel of physicians who were unaware of the screening history of the patients. The cause of death was ascertained based on the clinical course of the disease and information about any serious co-morbidity. Breast cancer was defined as the cause of death if the disease had progressed to distant sites and if this progression could not be ruled out as the cause of death of the patient.

The reference population consisted of inhabitants of Arnhem, a city located 20 kilometers north of Nijmegen, where mass screening was started in 1989 for women aged 50 to 69 years as part of the national programme in The Netherlands. The Arnhem patients were registered by the “Carcinoma Work Group”, which operated until 1991. With the aid of the local authorities, patients who had died or moved away from Arnhem could be identified. The cause of death of deceased patients was established in the same manner as that described above and by the same physicians as in Nijmegen.

For Arnhem, person-years of observation had to be calculated from the official census statistics published annually by the Dutch
Central Bureau of Statistics. These statistics keep track of the number of inhabitants of each sex, by year of birth, on 1 January of each calendar year. Although data for Nijmegen were available on an individual basis, woman-years were also calculated on the basis of the census statistics for the sake of comparability of the information. For each calendar year up to and including 1990, the mid-year population size was calculated as the number of woman-years of observation in that year.

Breast-cancer mortality rates in Nijmegen were based on data from patients in whom breast cancer had been diagnosed after the invitation to the first round of screening in 1977–1978. For 1977 and 1978, a population-time correction was made according to the exact entry dates. The mortality rates in Arnhem were based on data from patients diagnosed from 1 January, 1978, onwards, since this was close to the median date of the first invitation for the Nijmegen population (55% had been invited by then). Patients diagnosed with breast cancer before this date were excluded from the analysis. The ratio of the cumulative breast-cancer mortality rates (i.e., number of breast-cancer deaths in the entire study period divided by the total number of woman-years) was calculated, as well as the ratios of breast-cancer mortality rate over 3 periods. Confidence intervals (CI) were calculated using the method based on the standard deviation of the log-transformed point estimates (Rothman, 1986a).

RESULTS

In Nijmegen, 7261 women born between 1895 and 1909 had been invited for screening in the period 1977 to 1990. A total of 46% had participated in the screening programme at least once, and half of these women had taken part more than once. A marked decrease in the participation rate was observed as the round number and age increased, illustrated in Figure 1 for rounds 2, 5 and 8. In rounds 2 to 8, overall participation rates were 43%, 29%, 22%, 15%, 12%, 10% and 4% respectively.

In Nijmegen, 173 patients were diagnosed as having breast cancer, vs. 183 in Arnhem. Breast cancer had been diagnosed in Nijmegen: (1) after a positive screening examination in 57 patients, (2) after a negative screening mammogram (interval cancer) in 21 patients, (3) before the first invitation in 4 patients who had moved to Nijmegen after 1977, and (4) after a refused invitation in 91 non-participant cases.

Table I shows the number of patients who had died from breast cancer, also the woman-years of observation for each calendar year. Two deaths occurred in patients diagnosed before their first invitation who had moved to Nijmegen after 1978. For both populations, the breast-cancer mortality rates (5-year moving average) are displayed in Figure 2. Up to 6 years after the start of screening, the breast-cancer mortality rate in Nijmegen was higher than that in Arnhem. In the subsequent years, the rate in Nijmegen stabilized, but an increase was observed in the late eighties. In Arnhem, the rate reached its maximum after 10 years and continued to decrease afterwards.

Over the entire study period, breast-cancer mortality in Nijmegen was lower than in Arnhem: cumulative mortality-rate ratio = 0.80 (95% CI, 0.53–1.22). Table II shows the ratio of the breast-cancer mortality rates with 95% CI over several periods. In the first period of 4 years, the mortality-rate ratio was 1.44, in the second period of 4 years it was 0.81, whereas in the relevant observation period, 9 to 13 years after the start of screening, it was 0.53 (95% CI, 0.27–1.04).

DISCUSSION

According to the results, the effect of screening manifests itself approximately 7 years after the start of the programme and reaches its maximum after about 10 years. This is what one would expect if analyses include only patients in whom breast cancer was diagnosed after the start of the screening programme. The proportion of patients diagnosed after the start of the screening programme at least once was 46% (95% CI, 0.53–1.22).
 mortality rates (5-year moving average) in Nijmegen, if diagnosed after first invitation 1977–78, and in Arnhem, if diagnosed from 1978 onwards.

women who participated in the programme decreased gradually, so the effect of screening on breast-cancer mortality can also be expected to decrease gradually. It is likely that the effect will have diminished 15 to 20 years after the start of screening.

Could the observed mortality reduction be due to screening 46% of the population only, while half of these women had been screened at least twice? In an earlier study, the incidence of breast cancer in Nijmegen and Arnhem was compared in women aged 65 years and older. In the period 1979 to 1988, the incidence rate of breast cancer in Nijmegen (adjusted for age in 5-year categories: 65–69, 70–74, 75–79, 80–84 and 85+) equalled that in Arnhem (RR, 0.97; 95% CI, 0.83–1.14), whereas in the Nijmegen non-

participants, the incidence was much lower than that in Arnhem (RR, 0.72; 95% CI, 0.56–0.93). Therefore the incidence of breast cancer in the participants must have been much higher than in the non-participants (Van Dijck et al., 1996). We concluded that the women who do participate in the screening are at increased risk for breast cancer. As a consequence, actual participation may have a relatively large effect on breast-cancer mortality in the population.

An important question is whether the populations of Nijmegen and Arnhem would have had the same breast-cancer mortality in the absence of screening. This cannot be derived directly, but it can be analyzed using an indirect approach by comparing the incidence of breast cancer. For the period 1975 to 1990, Figure 3 shows the incidence rates of primary breast cancer (5-year moving averages) in Nijmegen and Arnhem in women born between 1895 and 1909. In almost every calendar year, the incidence in Nijmegen was lower than in Arnhem. It was only higher in Nijmegen in 1977 to 1981, when rounds 1 and 2 took place for this birth cohort. In the early eighties, the incidence rate in Nijmegen declined, possibly due to the start of screening in the late seventies. Table III shows the number of diagnosed patients and the woman-years of observation, as well as the incidence-rate ratio for 4 periods. The incidence-rate ratio was 0.90 (95% CI, 0.75–1.07), adjusted for these 4 periods (directly weighted pooled estimate (Rothman, 1986b, 1996c). Correction of the mortality-rate ratio over the relevant observation period 1986 to 1990 gave an estimate of 0.59 (95% CI, 0.30–1.16).
Besides incidence, prognosis is also a modifier of breast-cancer mortality. Differences in prognosis could result from differences in treatment between Nijmegen and Arnhem. In Nijmegen, 30% of the patients were diagnosed and treated at the University hospital, while the remainder were patients at the other Nijmegen hospital. At the latter, a “Diagnostic Mamma Team” has been established, comprising radiologists, pathologists, and surgeons from the 2 hospitals. Once a week, all the patients are discussed. The goal of these weekly discussions is to reduce the number of invasive diagnostic procedures. Although the patients from the 2 cities were treated according to protocols, the monitoring of diagnostic procedure may have influenced the decision for treatment.

A difference may have existed in the extent of misclassification of the cause of death. The procedures followed and the criteria used to ascertain the cause of death were identical for the Nijmegen and Arnhem patients. However, the physicians who made the classification were not blinded for city. Although unlikely, this may have led to differential misclassification. It is also possible that the information available in Nijmegen was more extensive than in Arnhem, for instance due to the “Diagnostic Mamma Team”. An indication that this may have been the case was the fact that the deaths of 4 Nijmegen patients had been classified as “death from other cause with metastases of breast cancer,” whereas no Arnhem patients had been classified as such. This category was used only during the last 3 years. Previously, deaths had been classified as either “due to breast cancer” or “due to other causes”.

Several case-referent studies have been conducted in Nijmegen. In women aged 67 years or older at entry, breast-cancer mortality after 6 years of follow-up for those screened at least once was 19% lower (RR, 0.81; 95% CI, 0.23-2.75) than in those who had never been screened (Verbeek et al., 1985). In the study reported in 1994, the follow-up period was 12 years (Van Dijck et al., 1994). In women aged 65 years and older who had been invited for screening at least twice, breast-cancer mortality in those who had participated in the most recent screening was 42% lower than in those who had rejected it (RR, 0.58; 95% CI, 0.24-1.41). In those aged 65 to 74, the reduction in breast-cancer mortality was 66% (RR, 0.34; 95% CI, 0.12-0.97). Our most recent study on women aged 65 years and older after 17 years of follow-up showed that breast-cancer mortality was 44% lower (RR, 0.56; 95% CI, 0.28-1.13) in women who had been screened regularly (i.e., after the 2 most recent invitations) than in women who had not been screened in the past 10 years (Van Dijck et al., 1996). In women aged 65 to 74 years the reduction in 3 case-referent studies, contrast was made between women who were screened and those who were not. The design of the present study was quite different, because contrast was made between the invited Nijmegen population, regardless of their actual screening history, and the uninvited Arnhem population. The most important reason for this design was to avoid bias due to self-selection. However, the price to be paid was a loss of contrast, because less than 50% of the invited population participated in at least one screening round.

The Swedish 2-county trial is the only other project with a long follow-up that included women aged 70 years and older. In that randomized study, the participation rate was 86% in women aged 65 to 69 and 77% in women aged 70 to 74 years. Women of over 74 years were excluded from all the analyses, because of the low participation rate of approximately 50%. After 14 years, the ratio of the cumulative risk (i.e., number of deaths to the number of women enrolled) in the women aged 65 to 74 years at entry was 0.68 (95% CI, 0.51-0.89), which is much smaller than in the Nijmegen invited population (cumulative rate ratio, 0.80). However, after the participation rate had been accounted for, the results compared very well.

The results of the present study, although in themselves inconclusive because of the wide confidence intervals, show a reduction in breast cancer mortality in women who were older than 65 years at entry to the screening programme. After 10 years, the reduction in breast cancer mortality may be as large as 40%. In an analysis of the positive and negative effects of screening after the age of 65 years, Boer and colleagues (1995) showed that, under optimistic assumptions, this balance may never become negative. Under pessimistic assumptions the positive effects may outweigh the negative effects until the age of 80 years. When the upper age limit of a screening programme is increased, however, the cost-effectiveness ratio will increase, for 2 reasons: the number of life-years gained will be less and the negative effects and the cost of screening will increase.

ACKNOWLEDGEMENTS

We are grateful to the Dutch “Nationale Ziekenfondsraad” for financial support. We thank Mr. J.D.M. Otten and Mr. E.P. Brummelkamp for gathering and processing the data; Ms. M.E. Eijkenberger for her help with the figures; Mrs. J. Abma-Hill for her linguistic comments; the Carcinoma Work Group Arnhem for gathering the Arnhem data; the Central Bureau of Statistics for the population data, and the local authorities of Nijmegen and Arnhem for providing the follow-up data on the patients.
