Brief communication

HLA-DRB1 in eight Finnish monozygotic twin pairs concordant for rheumatoid arthritis

HLA-DRB1 in eight Finnish monozygotic twin pairs concordant for rheumatoid arthritis.

This study presents the results of HLA-DRB1 typing of the eight monozygotic twin pairs with both members affected by rheumatoid arthritis (RA), sampled in the nationwide Finnish twin cohort. The shared epitope, associated with RA in case-control studies, was present in all eight twin pairs, being significantly more frequent than among RA patients in a recent Dutch case-control study. Furthermore, 4 out of 8 twin pairs were homozygous for the shared epitope, while in 73 Dutch healthy controls encoding the shared epitope only 13 (18%) were homozygous; this suggests a gene dose effect in RA susceptibility. Combining these results with data from other sources may help to clarify the contribution of HLA alleles in the genetic predisposition to RA.

While early reports (1, 2) showed an association of the serologically defined HLA-DR4 and -DR1 specificities with rheumatoid arthritis (RA), more recent case-control studies show that this disease is associated with HLA-DRB1 alleles encoding a short structural motif in the third hypervariable region, the "shared epitope" (SE). This shared epitope may be encoded by any of three highly homologous amino acid sequences at positions 67 to 74 of this molecule: LLEQKRAA, LLEQRRAA or LLERRRAA (single letter amino acid code: A = alanine, E = glutamic acid, K = lysine, L = leucine, Q = glutamine, R = arginine) (3, 4).

While case control studies in the general population help to define the association between DRB1 alleles and disease susceptibility, data from diverse sources are needed to describe the genetic model for a given disease, e.g. mode of inheritance, the number of genes involved or the relative contribution of HLA to genetic predisposition. Twin studies, assessing the frequency of disease concordance in mono- and dizygotic twins, are very informative in this respect (5–9).

In RA, among the twin studies performed, the Finnish twin cohort study (6, 7) is unique in one aspect: By linking the Finnish twin cohort with the Sickness Insurance Register nearly all relevant twins are included in the study, resulting in virtually complete ascertainment. In such a study the risk of bias is reduced, e.g. concordant twin pairs are not more likely to enter the study than discordant pairs. Avoiding these biases is important when differentiating between several genetic models. Since in RA these genetic models have to incorporate the effects of HLA-DRB1 alleles on RA risk, we performed HLA-DRB1 typing of the Finnish monozygotic concordant affected twins.

From 4137 monozygotic twin pairs, in total eight monozygotic twin pairs, both individuals fulfilling the 1987 criteria of the American College of Rheumatology for RA, were identified (6, 7). The sampling procedure, zygosity testing and clinical characteristics of these twins have been described elsewhere (6, 7). All 16 twin members were seropositive at some stage, 14 had erosive disease, 12 had been treated with gold and 7 had rheumatoid nodules. Peripheral blood was available from all individuals except patient 1A and 8B.

For HLA-typing DNA was isolated from peripheral blood, amplified in a polymerase chain reaction (PCR) using primers P1 and P2 specific for exon 2 (10), and screened using sequence specific (SSO) probes 1003 and 2810 described in the 11th workshop (11), probes 88–144, 88–148, 88–150, 88–151.
