(Received 11 March 2005; published 2 August 2005)

By studying the resonant tunneling of electrons through self-assembled ring-shaped (InGa)As quantum dots embedded in the quantum well of an (AlGa)As/GaAs/(AlGa)As heterostructure, we find evidence for the existence of excited states of the quantum dots which exhibit a $2p_z$-like character along the growth direction $z$. The states are investigated by magnetotunneling spectroscopy with magnetic fields applied parallel and perpendicular to $z$.

PACS number(s): 73.23.-b, 73.63.Kv, 73.40.Gk

In self-assembled semiconductor quantum dots (QDs), carriers are confined in all three spatial dimensions. This leads to a spectrum of discrete energy levels, similar to that of atoms. The analogy with atoms is strengthened by the observation of excitonic and electronic states with $s$, $p_z$, and $d$-like character, all of which have been observed in optical and tunneling spectroscopy studies. In addition, optical pumping experiments have provided evidence for shell-like filling of the electronic orbitals. However, in contrast to a real atom, a QD has a highly anisotropic confining potential, since its dimensions in the plane of growth (the wetting layer plane $x$-$y$) are typically an order of magnitude larger than that along the growth direction $z$. Hence spectroscopic investigations have been restricted mainly to states for which the excitations are confined to the $x$-$y$ plane.

In this paper, we study the electronic properties of QDs with an unusual ring-shape morphology, which can be generated under special growth conditions. We report experimental evidence for the presence of excited QD states with a $2p_z$-like character. States with $2p_z$ character have been observed previously for Si donors in a GaAs QW. For this study we use resonant tunneling heterostructure diodes in which a single layer of self-assembled (InGa)As quantum dots is embedded in an (AlGa)As/GaAs/(AlGa)As quantum well. The $2p_z$-like quasibound states are revealed by the presence of additional resonant peaks in the tunnel current. By combining photoluminescence and magnetotunneling spectroscopy with magnetic field $B$ applied along $z$ and in the $x$-$y$ plane, we show that these resonances correspond to electron tunneling into $2p_z$-like states with binding energies in the range $5$–$30$ meV below the edge of the continuum of the first excited two-dimensional (2D) subband of the GaAs QW.

Despite the ring-shape structure of the dots, we find no evidence in our tunneling data for states showing Aharonov-Bohm character.

Our device is a GaAs/Al$_{0.4}$Ga$_{0.6}$As double barrier electron resonant tunneling diode (RTD) grown by molecular beam epitaxy (MBE) on a (100)-oriented $n^+$ GaAs substrate. The conduction band profile of the device and the QD energy levels are shown schematically in Fig. 1(a). Two 8-nm-thick Al$_{0.4}$Ga$_{0.6}$As tunnel barriers define a 10-nm-thick GaAs QW, which contains a layer of (InGa)As QDs. Undoped GaAs spacer layers of width 50 nm separate the Al$_{0.4}$Ga$_{0.6}$As barriers from lightly $n$-doped ($n=2\times10^{17}$ cm$^{-3}$) GaAs layers of width 50 nm. Two $0.4\mu$m $n^+$ Si-doped GaAs layers form the outer electrical contacts of the device. The QW and QD layers were prepared as follows: after the growth of the first half of the QW, 1.85 monolayers of InAs were deposited to form the QD layer. The dots were then capped with 2 nm of GaAs and annealed for 90 s in an As$_2$ atmosphere. The GaAs growth was then resumed and the remaining 3 nm of the well was grown. This procedure leads to the transformation of the InAs layer into (InGa)As ring-shaped dot structures, which are commonly referred to as quantum rings (QRs). For comparison, experiments were also carried out on a control sample (C sample), grown with the same structure as the QD sample but without the InAs layer. The structures were processed into mesas with diameters between 50 and 200 μm, with an annular metallic top contact layer to provide optical access.

Atomic force microscope images of similarly prepared uncapped ring-shaped QD layers (with the growth terminated after the annealing stage) reveal a QD density of $7 \times 10^9$ cm$^{-2}$, see inset of Fig. 1(a). Cross-sectional scanning
Figure 1. (a) Schematic conduction-band profile under bias of our RTD incorporating ring-shaped (InGa)As QDs. The right inset indicates the wave-function symmetry of the 1s (bottom) and 2p_z (top) quasibound states of the QDs. Upper inset: AFM image of uncapped ring-shaped QDs. (b) XSTM image (50 × 17 nm) of a capped ring-shaped QD. The light areas are In-rich. The atomic layers are fully resolved.

Tunneling microscope (XSTM) images of similarly GaAs-capped ring-shaped QDs indicate a lateral diameter of ≈20 nm and a height of 3 nm [Fig. 1(b)]. Ring-shaped QDs have shown a very high intraband oscillator strength and a large excitonic electric dipole. Capacitance-voltage experiments in magnetic fields have also provided some evidence of Aharonov-Bohm states, related to magnetic flux quantization in the ring-shaped structure.

Figure 2 compares the current-voltage characteristics, I(V), of the QD and C samples, measured on 50 μm mesas. The C sample exhibits two strong resonant peaks in both forward and reverse bias, corresponding to electron tunneling into the E_1 and E_2 two-dimensional (2D) subbands of the QW [Fig. 1(a)]. Some of the features of the QD sample are typical of RTDs incorporating QDs. For example, the current in the QD sample is approximately one order of magnitude lower than in the C sample. This is attributed to the fact that most of the electrons that tunnel into the QW relax down to the lower energy states of the QDs. They then tunnel into the collector through the second barrier which has a relatively large height and low transmission coefficient. Secondly, the resonant peak at ±0.1 V observed in the I(V) curve of the C sample, which arises from resonant tunneling of electrons into the lowest QW subband, E_1, appears as a much weaker shoulder at ±0.1 V (indicated by the downward arrows in Fig. 2) in the I(V) of the QD sample. We attribute this shoulder to resonant tunneling into the lowest energy 2D subband of the QW which is formed by the combination of the residual (InGa)As wetting layer (WL) potential and the GaAs/Al_{0.4}Ga_{0.6}As QW potential. In the QD sample, the disorder associated with the QD layer disrupts the low k states of the WL subband and tends to broaden and suppress the associated resonance in I(V). Evidence for this attribution is provided by the magnetic field dependence of the I(V) curves as described later in the paper.

In forward bias, the QD sample shows a strong resonance associated with tunneling into the second QW subband E_2. The corresponding peak in reverse bias is much weaker. A resonant peak for bias ≈-1.7 V is also observed in the I(V) of the QD sample. We attribute this to resonant tunneling of electrons into the highest QW subband, E_3. In the C sample, the E_3 subband is expected to be too high in energy to be revealed in I(V). In contrast, the introduction of the InAs layer lowers the energy of the E_3 subband below the top of the barriers, giving rise to a resonant peak in I(V).

We have examined the low bias-low current (1-100 pA) part of the I(V) characteristics in some detail but found no evidence of peaks corresponding to resonant tunneling into the ground states of the QDs, which have been reported previously in other resonant tunneling devices incorporating QDs. We attribute this to the fact that the energy levels of the QD ground states lie below the chemical potential in the emitter at all biases so energy-conserving tunneling transitions through the dots are not allowed.

We now focus on the most striking feature of the I(V) characteristics of the QD sample, namely the presence of four additional resonant peaks in reverse bias, in the range between the E_1 and the E_2 subband resonant peaks. We have measured the I(V) curves of 30 different mesas with different diameters, taken from different sections of the 5 cm diameter MBE wafer. We observe this series of additional resonant peaks in all 30 mesas. Moreover, all of the mesas have essentially identical current-density characteristics, J(V), when the measured current is divided by the cross-sectional area of the mesas. This result indicates that the peaks are due to a macroscopic property of the MBE wafer and not to local or mesoscopic effects of a given mesa.

The inset of Fig. 2 shows the quantum dot photoluminescence (PL) spectrum obtained at zero bias, with excitation by the 632.8 nm line of a HeNe laser. The PL spectrum consists...
the resonances shift to higher negative bias with increasing applied field. By studying the dependence of the voltage position of the resonant peaks in $I(V)$ as a function of in-plane magnetic field, $B_{xy}$, the energy-vector dispersion curve, $\epsilon(k)$, of the QW can be mapped. Also for tunneling into localized states in the QW, the dependence of the amplitude of the resonant peaks on $B_{xy}$ provides a powerful means for imaging the electron wave function.

In order to study the character of peaks $A$ to $D$ we use magnetotunneling spectroscopy (MTS). In MTS, a magnetic field is applied parallel to the QW plane and is used to tune the in-plane momentum $\hbar k$ of the tunneling carrier (electron or hole); the energy of the tunneling electron is adjusted by the applied bias. By studying the dependence of the voltage position of the resonant peaks in $I(V)$ as a function of in-plane magnetic field, $B_{xy}$, the energy-vector dispersion curve, $\epsilon(k)$, of the QW can be mapped. Also for tunneling into localized states in the QW, the dependence of the amplitude of the resonant peaks on $B_{xy}$ provides a powerful means for imaging the electron wave function.

Figure 3(a) shows the effect on the $I(V)$ curves of $B_{xy}$. With increasing $B_{xy}$, the weak shoulder associated with electron tunneling into the wetting layer subband $E_1$ develops into a well-defined resonant peak, as has been reported in earlier experiments on RTDs incorporating QDs. The magnetic field $B_{xy}$ provides the tunneling electrons with an in-plane momentum $\hbar k = eB_{xy}\Delta s$, where $\Delta s$ is the tunneling distance [see Fig. 1(a)]. The additional kinetic energy associated with this momentum is provided by the applied bias. At sufficiently large values of $k (\approx 10^8 m^{-1})$ the QD-induced disorder has less effect on the $E_1$ subband states and the resonant tunneling peak in $I(V)$ is restored. Also note that all of the resonances shift to higher negative bias with increasing $B_{xy}$. However, while the amplitude of the $E_1$ resonance increases as expected for tunneling into a QW subband, that of peaks $A$ to $D$ falls off with increasing $B_{xy}$ and, at 11 T, the peaks are barely visible in $I(V)$.

The $I(V)$ curves measured in magnetic field $B_z$, applied parallel to the growth direction [see Fig. 3(b)] also reveal the difference in character of peaks $A$ to $D$ compared to peak $E_1$. Peaks $A$ to $D$ are only slightly affected by $B_z$, whereas the $E_1$ resonance splits due to the formation of Landau levels (LLs) in the QW. An extra peak due to resonant tunneling of electrons from the emitter into the second ($N=1$) LL appears for $B_z \approx 18$ T, in addition to the principal resonance associated with $N=0$ [arrows in Fig. 3(b)].

The absence of LL splitting for peaks $A$ to $D$ with increasing $B_z$ indicates that they are due to electron tunneling into localized states rather than into bandlike states. This is supported by the observation of a decrease in amplitude of these peaks with increasing $B_{xy}$, which has been observed and investigated in detail for electron tunneling into conventional self-assembled quantum dots and impurity states. The inset of Fig. 3(a) shows the dependence of the amplitude of the differential conductance ($G=dI/dV$) on $B_{xy}$ for peak $A$. (b) The field $B_z$ is perpendicular to the QW plane. $B_z$ is increased from 0 (bottom curve) to 30 T (top curve) in 2 T steps. In both panels the curves are displaced along the vertical axis for clarity.

FIG. 3. $I(V)$ curves for QD sample at different magnetic fields. (a) The field $B_{xy}$ is applied parallel to the QW plane. $B_{xy}$ is increased from 0 (bottom curve) to 11 T (top curve) in 1 T steps. The inset shows the dependence of the amplitude of the differential conductance ($G=dI/dV$) on $B_{xy}$ for peak $A$. (b) The field $B_z$ is perpendicular to the QW plane. $B_z$ is increased from 0 (bottom curve) to 30 T (top curve) in 2 T steps. In both panels the curves are displaced along the vertical axis for clarity.

To determine the energy, magnetic field dependence, and character of the states associated with peaks $A$ to $D$, we need to consider the way in which the applied voltage is distributed across the device. We define an electrostatic leverage factor, $f$, as the ratio between the total applied voltage $V$ and the portion $V_1$ dropped between the emitter and the center of
with a small $B_f\approx B_f^{\text{LL}}$, indicated by downward arrows in Fig. 4(a), arises from sequential depopulation with increasing $B_z$ of the LLs of the degenerate two-dimensional electron gas in the emitter accumulation layer. For a fixed applied bias, the $B_f^{\text{LL}}$ value gives us the sheet density $n_s$ of the electron in the emitter accumulation layer according to the relation

$$n_s(V) = 2eB_f^{\text{LL}}(V)/\hbar.$$  

(1)

The magneto-oscillations at higher magnetic fields, indicated by upward arrows in Fig. 4(a), are due to electrons tunneling from the emitter accumulation layer $E_0$ into the LLs associated with the $E_1$ subband of the QW. At constant bias and with increasing $B_z$, a resonant feature appears in the current when the following energy conservation condition is satisfied:

$$E_0 - E_1 = N\hbar e B_f/m_e + (\hbar\omega_{\text{LO}}).$$  

(2)

Here $m_e$ is the in-plane (or cyclotron) mass in the QW, $N$ is an integer, and the term in brackets indicates the possibility of the emission of a longitudinal optical (LO) phonon in the tunneling transition. This series is also periodic in $1/B$ with a fundamental field $B_f^{\text{GW}}(V) = (E_0 - E_1)m_e\hbar e/V$, for the case when no LO phonons are emitted. Since $(E_0 - E_1)/e$ is the voltage drop across the effective width $\Delta s$ of the first tunnel barrier, the electrostatic leverage of the device is simply $f = m_e\sqrt{V/B_f^{\text{GW}}(V)}$. It is also interesting to note that since $(E_0 - E_1)$ depends linearly on $n_s$, the values of $B_f^{\text{GW}}$ and $B_f^{\text{LL}}$ obey the simple relation

$$\frac{\partial B_f^{\text{GW}}}{\partial B_f^{\text{LL}}}(V) = c^2 m_e \Delta s/\pi e \epsilon_s \hbar^2 = 4\Delta s/a_0,$$  

(3)

where $a_0 = 10$ nm is the Bohr radius in GaAs. A simple electrostatic model based on the Fang-Howard variational wave function gives the effective tunnel distance from the emitter into the QW, $\Delta s = 26$ nm at $V = -1$ V, so that $\partial B_f^{\text{GW}}/\partial B_f^{\text{LL}} \approx 10$. This relation agrees with the experimental value over the full bias range.

At low bias ($\approx 0.5$ V), the measured value of $B_f^{\text{GW}}$ gives $f \approx 4$, which agrees with that determined by a simple electrostatic model and the layer composition of our device. For higher biases, corresponding to resonances A to D, $B_f^{\text{GW}}$ increases more slowly with $V$, thus indicating charge build-up in the QW and a larger value of $f$ ($f \approx 10$ at $V = -1$ V). The large jump in the measured value of $B_f^{\text{GW}}$ and $B_f^{\text{LL}}$ at a voltage of $\approx 1.4$ V, where the current falls abruptly just beyond the resonant peak $E_1$, indicates the discharge of electrons from the QW and the corresponding increase in $n_s$, which is required to maintain the voltage drop across the device.

This analysis allows us to convert the voltage position of different resonances in $I(V)$ into an energy scale for the electron states in the QW. Figure 5(a) shows the magnetic field dependence of the energy of the quantum states associated with the resonant features in $I(V)$ for $B$ perpendicular to $z$. Two features of these plots are noteworthy. First, the parabolic shift of $E_1$ to higher energies with increasing $B_z$, i.e., increasing $k$, indicates that this feature corresponds to tunneling into energy-dispersed $k$ states of the QW subband [see
bulk GaAs and InAs, we obtain a value of \( \Delta_2 \) between 4 and 10 T, which is characteristic of quantum interaction, as evident from Fig. 5(c). The magnitude of the anticrossing energy suggests that the coupling of the cyclotron motion with the z-motion is relatively small (\( \ll \hbar \omega_c \) at the anticrossing point).

Based on this analysis of the data we can now build up a model for the electronic states in the QW. The four additional resonances A to D in \( I(V) \) and the four component-PL spectra indicate a multimodal distribution of QD sizes, distributed into four main size groups. We propose that peaks A to D arise from resonant tunneling of electrons into discrete excited state energy levels associated with the QDs. These states are well above the edge of the \( E_1 \) subband but are quasidegenerate with respect to the edge of the \( E_2 \) QW subband with a small binding energy (\( \ll 30 \) meV). Their eigenfunctions have \( 2p_z \)-like (\( \ell_z = 0 \)) character, and would therefore have two lobes along \( z \), as indicated schematically in Fig. 1(a). The corresponding electronic \( 1\text{~s} \) ground states of the QDs are bound at larger energies (\( \approx 100 \) meV) with respect to the edge of \( E_1 \).

A puzzling aspect of the \( I(V) \) curves is the asymmetry with respect to bias and the complete absence of the resonant peaks in forward bias corresponding to A, B, C, and D. Note that the \( E_2 \) resonance in forward bias in the QD sample is as well-defined as in the control sample, indicating that the InAs QD layer produces a negligible effect on the \( E_2 \) states at this bias. We suggest that, in this case, the node of the eigenfunction is very close to the InAs layer so that the perturbation on the electron tunneling into \( E_2 \) is minimal (see Fig. 6). In contrast, a reverse bias acts to shift the wave function away from the InAs layer. In this case, the probability density of the wave functions at the InAs layer could be sufficient to lead to weak binding of the \( 2p_z \)-like states to the QDs (see Fig. 6). The perturbing effect of the InAs layer could also explain the observed significant reduction of the amplitude of the \( E_2 \) resonance in reverse bias, as a sizeable fraction of the area of the heterostructure is influenced by the QD potential. This is evident from the AFM and XSTM images [Fig. 1(a)]. Therefore the number of pure \( E_2 \)-subband

FIG. 5. (a) and (b) Dependence of the energies of the electron states in the QW on (a) \( B_z \) and (b) \( B_x \) as measured relative to the edge of the \( E_1 \) subband. (c) Detail of the differential conductance of the QD sample showing the anticrossing between the \( N=1 \) Landau level peak and peak A.

FIG. 6. Diagram showing the possible effect of reverse and forward bias on the \( E_2 \) subband. The probability density is obtained from an effective mass calculation of the energy eigenstates of a 10-nm-thick GaAs/Al_{0.4}Ga_{0.6}As QW in the presence of a forward and reverse electric field corresponding to that of our experiment.
The observation of the $2p_z$-like states is not strictly related to the ring shape of the QDs and could be also revealed in conventional QDs, in principle. However, the QDs considered in this work appear to be distributed into four distinct and narrow energy ranges of a multimodal distribution, which we believe facilitates the observation of well-defined resonances in the current-voltage characteristics. In addition, the quantum rings extend significantly along the $z$ direction (their height is about 3 nm), which should lead to a strong perturbation of the first excited state of the well and the formation of bound $2p_z$-like states.

To summarize, we have investigated the electronic properties of ring-shaped self-assembled quantum dots using magnetotunneling and photoluminescence spectroscopy. We observe unusual resonant features in the current-voltage characteristics and provide evidence that they arise from electron tunneling into quasibound quantum dot states with $2p_z$-like character. These states have $\langle f_z \rangle = 0$. Despite the ringlike shape of the dots, there is no evidence of magnetic flux quantization effects in the magnetotunneling spectra. Resonant voltage-controlled filling of these excited states could provide a means of exciting infrared intraband transitions of QDs.
