Measurement of the $\Lambda^0_b$ lifetime in the decay $\Lambda^0_b \rightarrow J/\psi \Lambda^0$ with the DØ Detector

We present measurements of the $A^0$ lifetime in the exclusive decay channel $A^0 \rightarrow J/\psi A^0$, with $J/\psi \rightarrow \mu^+\mu^-$ and $A^0 \rightarrow \pi^+\pi^-$, the $B^0$ lifetime in the decay $B^0 \rightarrow J/\psi K^0_s$ with $J/\psi \rightarrow \mu^+\mu^-$ and $K^0_s \rightarrow \pi^+\pi^-$, and the ratio of these lifetimes. The analysis is based on approximately 250 pb$^{-1}$ of data recorded with the D0 detector in $p+p$ collisions at $\sqrt{s}=1.96$ TeV. The $A^0$ lifetime is determined to be $\tau(A^0) = 1.22^{+0.18}_{-0.15}(\text{stat}) \pm 0.04(\text{syst})$ ps, the $B^0$ lifetime $\tau(B^0) = 1.40^{+0.10}_{-0.09}(\text{stat}) \pm 0.03(\text{syst})$ ps, and the ratio $\tau(A^0)/\tau(B^0) = 0.87^{+0.04}_{-0.05}$. In contrast with previous measurements using semileptonic decays, this is the first determination of the $A^0$ lifetime based on a fully reconstructed decay channel.

Calculations based on a simple quark-spectator model [1] predict that the lifetimes of all $b$ hadrons are equal. When non-spectator effects are taken into account, they give rise to a lifetime hierarchy of $\tau(B^+) \approx \tau(B^0) \approx \tau(A^0) \gg \tau(B_c^+)$. Measurements of $b$-hadron lifetimes therefore provide means to determine the importance of non-spectator contributions in $b$-hadron decays. For comparison with theory, measure-
mements of lifetime ratios are preferred over individual lifetimes. The ratio \( \tau(\Lambda^0_b)/\tau(B^0_s) \) has been the source of theoretical study since early calculations [3] predicted a value greater than 0.90, almost two sigma away from the measurement average [4], 0.800 ± 0.053. Recent calculations [5] of this ratio that include higher order effects have reduced this difference. A current compilation [4] of lifetime ratio data for b hadrons is consistent with early calculations [6] that include non-spectator effects. Previous measurements of \( \tau(\Lambda^0_b) \) used semileptonic decay channels that suffer from uncertainties arising from undetected neutrinos. A measurement of the lifetime using fully reconstructed \( \Lambda^0_b \) decays is free from the neutrino ambiguities. The Tevatron Collider at Fermilab is the only operating accelerator where \( \Lambda^0_b \) baryons are being produced and studied.

In this Letter we report a measurement of the \( \Lambda^0_b \) lifetime in the decay channel \( \Lambda^0_b \to J/\psi \Lambda^0 \), and its ratio to the \( B^0 \) lifetime from the \( B^0 \to J/\psi K^0_S \) decay channel. This \( B^0 \) decay channel is chosen because of its similar topology to the \( \Lambda^0_b \) decay. The \( J/\psi \) is reconstructed in the \( \mu^+ \mu^- \) decay mode, the \( \Lambda^0 \) in \( p\pi^- \), and the \( K^0_S \) in \( \pi^+ \pi^- \); throughout this Letter the appearance of a specific charge state will also imply its charge conjugate. The data used in this analysis were collected during 2002-2004 with the DØ detector in Run II of the Tevatron Collider at a center-of-mass energy of 1.96 TeV, and correspond to an integrated luminosity of approximately 250 pb\(^{-1}\).

The components of the DØ detector [7] most relevant for this measurement are the charged-particle tracking systems and the muon detector. The DOI tracker consists of a silicon microstrip tracker (SMT) and a central fiber tracker (CFT) that are surrounded by a superconducting solenoid magnet that produces a 2 T central magnetic field. The SMT has approximately 800,000 individual strips, with a typical pitch of 50–80 \( \mu \)m, and a design optimized for tracking and vertexing capability for \(|\eta| < 3\) \((\eta = -\ln[\tan(\theta/2)]\) and \(\theta\) is the polar angle). The system has a six-barrel longitudinal structure interspersed with sixteen disks. Each barrel consists of four layers arranged axially around the beam and the disks are placed perpendicular to the beam. The CFT has eight thin coaxial barrels, each supporting two doublets of overlapping scintillating fibers of 0.835 mm diameter; one doublet being parallel to the collision axis, and the other alternating by ±3° relative to the axis. For charged particles, the resolution for the distance of closest approach as provided by the tracking system is approximately 50 \( \mu \)m for tracks with \( p_T \approx 1 \) GeV/c, and improves asymptotically to 15 \( \mu \)m for tracks with \( p_T \geq 10 \) GeV/c. \( p_T \) is the component of the momentum perpendicular to the beam pipe. Preshower detectors and electromagnetic and hadronic calorimeters surround the tracker. A muon system is located beyond the calorimeter, and consists of multilayer drift chambers and scintillation trigger counters preceding 1.8 T toroidal magnets, followed by two similar layers beyond the toroids. Muon identification for \(|\eta| < 1\) relies on 10 cm wide drift tubes, while 1 cm mini-drift tubes are used for \(1 < |\eta| < 2\).

Primary vertex (PV) candidates are determined for each event by minimizing a \( \chi^2 \) function that depends on all the tracks in the event and a term that represents the beam spot constraint. The beam spot is the run-by-run average beam position, where a run typically lasts several hours. The beam spot is stable during the periods of time when the proton and antiproton beams are kept colliding continuously and can be used as a constraint for the primary vertex fit. The initial primary vertex candidate and its \( \chi^2 \) are obtained using all tracks. Next, each track used in the \( \chi^2 \) calculation is removed temporarily and the \( \chi^2 \) is calculated again; if the \( \chi^2 \) decreases by 9 or more, this track is discarded from the PV fit. This procedure is repeated until no more tracks can be discarded. Additional primary vertices are obtained by applying the same algorithm to the discarded tracks until no more vertices are found.

We base our data selection on defined objects such as charged tracks and muons. Although we do not require any specific trigger to select our sample, most of the events selected fire dimuon or single muon triggers. Preliminary selection of dimuon events requires the presence of at least two muons of opposite charge reconstructed in the tracker and the muon system. We require that at least one of the muon candidates consists of a central track, defined by hits in the SMT and CFT, matched with muon track segments in all three layers of the muon system. For the second muon, we require a central track matched with hits in at least the innermost layer of the muon system. The sample of \( J/\psi \to \mu^+ \mu^- \) candidates consists of events with at least two muons, with trajectories constrained in a fit to a common vertex. The fit must have a \( \chi^2 \) probability greater than 1%, and the invariant mass of the dimuons must be in the range 2.80 < \( M_{\mu\mu} \) < 3.55 GeV/c\(^2\). To reconstruct \( \Lambda^0_b \) and \( B^0 \) candidates, the \( J/\psi \) events are examined for \( \Lambda^0_b \) and \( K^0_S \) candidates. The \( \Lambda^0 \to p\pi^- \) candidates are required to have two tracks of opposite charge which must originate from a common vertex with a \( \chi^2 \) probability greater than 1%. A candidate is selected if the mass of the proton-pion system after the vertex-constrained fit falls in the 1.100 < \( M_{px} \) < 1.128 GeV/c\(^2\) window. The proton mass is assigned to the track of higher momentum, and the \( p_T \) of the \( \Lambda^0 \) is required to be greater than 2.4 GeV/c. The \( K^0_S \to \pi^+\pi^- \) selection follows the same criteria, except that the mass window is 0.440 < \( M_{\pi\pi} \) < 0.525 GeV/c\(^2\), and \( p_T > 1.8 \) GeV/c.

We reconstruct the \( \Lambda^0_b \) and \( B^0 \) by performing a constrained fit to a common vertex for either the \( \Lambda^0 \) or \( K^0_S \) and the two muon tracks, with the latter constrained to the \( J/\psi \) mass of 3.097 GeV/c\(^2\) [4]. Because of their long decay lengths, a significant fraction of \( \Lambda^0 \) and \( K^0_S \) will decay outside the SMT. Therefore, to maintain good ef-
ficiency, no SMT hits are required on the tracks of the decay particles. To reconstruct the $\Lambda_c^0$ ($B^0$), we first find the $\Lambda^0$ ($K^0_S$) decay vertex, and then extrapolate the momentum vector of the ensuing particle and form a vertex with it and the two muon tracks belonging to the $J/\psi$. The precision of the $\Lambda_c^0$ ($B^0$) vertex position is dominated by the two muon tracks from the $J/\psi$. If more than one candidate is found in the event, the candidate with the best $\chi^2$ probability is selected as the $\Lambda_c^0$ ($B^0$) candidate.

We determine the lifetime of a $\Lambda_c^0$ or $B^0$ by measuring the distance traveled by each $b$-hadron candidate in a plane transverse to the beam direction, and then applying a correction for the Lorentz boost. We define the transverse decay length as $L_{xy} = \frac{p_T}{\beta\gamma p_T}$, where $L_{xy}$ is the vector that points from the primary to the secondary vertex and $p_T$ is the transverse momentum vector of the $b$ hadron. The proper decay length (PDL) for a $b$-hadron candidate is then given by:

$$\text{PDL} = L_{xy} \frac{cM_B}{p_T},$$

where $(\beta\gamma)_B$, and $M_B$ are the transverse boost and the mass of the $b$ hadron, respectively. In our measurement, the value of $M_B$ in Eq. 1 is set to the PDG mass value of $\Lambda_c^0$ or $B^0$ [4]. In our final selection of $\Lambda_c^0$ and $B^0$ candidates, we require an error of less than 100 $\mu$m on the PDL and we also require a total momentum greater than 5 GeV/c.

We perform an unbinned likelihood fit to measure the $\Lambda_c^0$ and $B^0$ lifetimes. The inputs for the fit are the mass, PDL and PDL error of the candidates. Candidates with invariant masses in the range of 5.1 to 6.1 GeV$/c^2$ for the $\Lambda_c^0$ and 4.9 to 5.7 GeV$/c^2$ for the $B^0$ are selected; these ranges include sideband regions that are used to model the PDL distributions of backgrounds. The likelihood function, $\mathcal{L}$, is defined by:

$$\mathcal{L} = \prod_{j=1}^{N} \left[ f_s S_M(M_j)S_L(\lambda_j, \sigma_j) + (1 - f_s) B_M(M_j)B_L(\lambda_j, \sigma_j) \right],$$

where $N$ is the total number of selected events, $f_s$ is the fraction of signal events in the sample, $S_M$ and $B_M$ are the probability distribution functions used to model the mass distributions for signal and background, respectively, and $S_L$ and $B_L$ model the distributions of proper decay lengths for signal and background. The likelihood function, $\mathcal{L}$, is defined by:

$$\mathcal{L} = \prod_{j=1}^{N} \left[ f_s S_M(M_j)S_L(\lambda_j, \sigma_j) + (1 - f_s) B_M(M_j)B_L(\lambda_j, \sigma_j) \right],$$

where $\lambda_j$ and $\sigma_j$ represent the PDL and its error respectively for a given event $j$, and the $s$ parameter is introduced in the fit to account for a possible misestimate of $\sigma_j$. The PDL distribution for background is described by a sum of a resolution function representing the zero-lifetime component, negative and positive exponential decay functions modeling combinatorial background, and an exponential decay that accounts for long-lived heavy flavor decays. We minimize $-2 \ln \mathcal{L}$ to extract the parameters: $\sigma(\Lambda_c^0) = 366 \pm 54 \mu$m and $\sigma(B^0) = 419 \pm 32 \mu$m.

We estimate the systematic uncertainty due to the resolution on the PDL by using two Gaussian functions for the resolution model. The contributions to the systematic uncertainty from the model describing background PDLs are studied by varying the parameters: (i) the exponential functions are replaced by exponentials convoluted with the resolution function of Eq. 3, (ii) a uniform background is added to account for outlier events (this has only a negligible effect), and (iii) the positive and negative short-lived lifetime components are forced to be symmetric. To study the systematic uncertainty due to the model for the mass distributions, we vary the shapes of the mass distribu-

The lifetime of the long-lived component of the background varies with mass. This results in an uncertainty in the decay constant of the background under the mass peaks. We obtain the systematic uncertainty due to this effect by modelling the long-lived background with two exponentials instead of a single exponential. The decay constant of one of the two exponentials is determined from a fit in the low-mass sideband, and the other decay constant is determined from the high-mass sideband. The low-mass sideband is defined as the mass window 4.900-5.149 GeV/$c^2$ for $B^0$ and 5.100-5.456 GeV/$c^2$ for $\Lambda_b^0$ and the high-mass sideband as 5.389-5.700 GeV/$c^2$ and 5.768-6.100 GeV/$c^2$ respectively. We perform the fit incorporating the linear combination of exponentials with the decay constants fixed to the values obtained in the low- and high-mass sidebands fits and allowing the coefficients of the linear combination to float. The systematic uncertainty quoted is the difference between the values we get from this fit and the nominal.

We also study the contamination of the $\Lambda_b^0$ sample by $B^0$ events that pass the $\Lambda_b^0$ selection. From Monte Carlo studies, we estimate that 19 $B^0$ events are reconstructed as $\Lambda_b^0$ events. The invariant masses of the $B^0$ events entering the $\Lambda_b^0$ sample are distributed almost uniformly across the entire mass range, and do not peak at the $\Lambda_b^0$ mass. Their proper decay lengths therefore tend to be incorporated in our model of the long-lived heavy-flavor component of the background. To estimate the systematic uncertainty due to this contamination, we fit the mass and proper decay length distributions of the misidentified events in the MC samples, add this contribution to the likelihood with fixed parameters, and perform the fit again. The difference between the two results is quoted as the systematic uncertainty due to the contamination.

The fitting procedure is tested for the presence of biases by generating 1000 Monte Carlo experiments, each with the same statistics as our data samples. For the generated events, the PDL errors are taken from data, and the mass and PDL distributions are described by the probability distribution functions used in data, with parameters obtained from the fit. The fits performed on these Monte Carlo experiments indicate that there is no bias inherent in the procedure.

We also perform several cross-checks of the lifetime measurements. In particular, a fit is done where the back-

ground is modeled using only sideband regions, the $J/\psi$ vertex is used instead of the $b$-hadron vertex, the mass windows are varied, the reconstructed $b$-hadron mass is used instead of the Particle Data Group [4] value, and the sample is split into different pseudorapidity regions or different regions of azimuth. All results obtained with these variations are consistent with our central values.

The results of our measurement of the $\Lambda_c^0$ and $B^0$ lifetimes are summarized as:

$$\tau(\Lambda_c^0) = 1.22^{+0.22}_{-0.18} \pm 0.04 \text{ (stat) ps}, \quad (4)$$

$$\tau(B^0) = 1.40^{+0.11}_{-0.10} \pm 0.03 \text{ (stat) ps}. \quad (5)$$

These can be combined to determine the ratio of lifetimes:

$$\frac{\tau(\Lambda_c^0)}{\tau(B^0)} = 0.87^{+0.17}_{-0.14} \pm 0.03 \text{ (stat)}, \quad (5)$$

where we determine the systematic uncertainty of the ratio by varying each parameter in the two samples simultaneously and quoting the deviation in the ratio as the systematic uncertainty due to that source.

In conclusion, we have measured the $\Lambda_c^0$ lifetime in the fully reconstructed exclusive decay channel $J/\psi\Lambda_c^0$. This is the first time that this lifetime has been measured in an exclusive channel. The measurement is consistent with the world average, $1.229 \pm 0.080 \text{ ps}$ [4], and the $\Lambda_c^0$ to $B^0$ ratio of lifetimes is also consistent with theoretical predictions [3, 5, 6].
