Abstract

The purpose of this study was to obtain a better understanding of neuronal responses to correlated input, in particular focussing on the aspect of synchronization of neuronal activity. The first aim was to obtain an analytical expression for the coherence between the output spike train and correlated input and for the coherence between output spike trains of neurons with correlated input. For Poisson neurons, we could derive that the peak of the coherence between the correlated input and multi-unit activity increases proportionally with the square root of the number of neurons in the multi-unit recording. The coherence between two typical multi-unit recordings (2 to 10 single-units) with partially correlated input increases proportionally with the number of units in the multi-unit recordings. The second aim of this study was to investigate to what extent the amplitude and signal-to-noise ratio of the coherence between input and output varied for single versus multi-unit activity and how they are affected by the duration of the recording. The same problem was addressed for the coherence between two single-unit spike series and between two multi-unit spike series. The analytical results for the Poisson neuron and numerical simulations for the conductance-based leaky integrate-and-fire neuron and for the conductance-based Hodgkin-Huxley neuron show that the expectation value of the coherence function does not increase for a longer duration of the recording. The only effect of a longer duration of the spike recording is a reduction of the noise in the coherence function. The results of analytical derivations and computer simulations for model neurons show that the coher-
ence for multi-unit activity is larger than that for single-unit activity. This is in agreement with the results of experimental data obtained from monkey visual cortex (V4). Finally, we show that multi-taper techniques greatly contribute to a more accurate estimate of the coherence by reducing the bias and variance in the coherence estimate.
1 Introduction

The recent advent of multiple electrode recording technology makes it possible to study the simultaneous spiking activity of many neurons. This allows us to explore how stimuli are encoded by neuronal activity and how groups of neurons act in concert to define the function of a given brain region. However, in spite of the considerable technological developments and the advanced analysis tools (for an overview, see Brown et al., 2004) there are many fundamental questions regarding the interpretation of multi-unit activity.

The gold standard in animal neurophysiology has been thought to be the study of isolated single-units for a long time. However, it appears as if the use of measures of neuronal aggregate activity, like multi-unit or local field potential recordings, greatly enhances the sensitivity of correlation and coherence analyses (see e.g. Baker et al., 2003; Rolls et al., 2003). This empirical observation is not yet understood. Related to this is the question whether a multi-unit recording for time T and consisting of m single-units with the same correlated input carries the same information as a single-unit recording for time mT?

Many studies (see e.g. Singer and Gray, 1995; Kreiter and Singer, 1996; Engel et al., 2001; Fries et al., 2001a) have so far demonstrated that neurons in early and intermediate visual cortex in cat and macaque exhibit significant correlated fluctuations in their responses to visual stimuli. These cells undergo attention-modulated fluctuations in excitability that enhance temporal coherence of the responses to visual stimuli (Fries et al., 2001b, 2002). The coherence is an important parameter, since it provides a measure for the similarity between two signals. Moreover, coherence among subthreshold membrane potential fluctuations likely expresses functional relationships during states of
expectancy or attention, allowing the grouping and selection of distributed neuronal responses for further processing (Fries et al., 2001a). The coherence between spike activity and local field potential was larger for multi-unit activity than for single-unit activity. Along the same lines, Baker et al. (2003) studied the cross-correlation and coherence between local field potentials and neural spike trains in monkey primary motor cortex. They concluded that a (small) population of neurons is necessary to encode the cortical oscillatory signal, i.e. the rapid modulations of synaptic input reflected in the oscillatory local field potential, effectively.

Several studies reported a lack of evidence for synchronized neuronal activity. For example, Tovee and Rolls (1992), in the inferior temporal visual cortex and Luck et al. (1997) did not observe clear synchronization in neuronal responses in V2 and V4. However, Kreiter and Singer (1996) did find clear synchronization in the middle temporal area (MT) if two cells were activated by the same stimulus. Besides recording in different recording areas and the use of different types of stimuli, also the statistical analysis technique might play an important role in detecting synchronization. Advanced multitaper techniques (Percival and Walden, 2002) have proven to be useful in estimating coherence between spike trains and local field potentials by improving the signal-to-noise ratio (Pesaran et al., 2002; see also Jarvis and Mitra, 2001). These multitaper techniques improved the significance of synchronized oscillatory neuronal activity.

The aim of this study was threefold. First, we wanted to obtain a quantitative understanding of the interpretation of correlated output spike trains in terms of correlated input (indirectly related to the local-field potential) to the neurons. In order to do so, we started with a network of simple Poisson neurons, the behavior of which could be analyzed analytically. This simple model
was then made more realistic by replacing the Poisson neurons by conductance-based neurons. The second aim of this study was to investigate to what extent the shape, amplitude and signal-to-noise ratio of the coherence between input and output varied for single versus multi-unit activity and whether the recording of single-unit activity over a long period of time could produce the same cross correlation and coherence with local field potential as multi-unit activity over a shorter period of time. We addressed the same question for the coherence between two spike outputs, both for two single and for two multi-unit spike series. The third aim of this study was to investigate the effectiveness of analyses techniques in revealing coherent activity in multi-unit activity. These three topics were investigated by comparing the results of coherence for single- and multi-unit activity in theoretical analyses for Poisson neurons, in computer simulations for conductance-based model neurons, and for data measured in monkey visual cortex (V4) (Fries et al., 2001b).

2 Methods and Theory

In order to obtain a better insight into the coherence between the local-field potential (LFP) at the one hand and single- or multi-unit activity at the other hand and in the coherence between spike trains of neurons that receive partially correlated input, we will start with a simple model (see Fig. 1). The local field potential reflects mainly the sum of postsynaptic potentials from local cell groups (Buzsáki, 2004). Therefore, the local field potential is seen to be indirectly related to the correlated input of neurons. We consider groups of neurons receiving correlated input that is reflected in a simulated LFP. We therefore modeled those neurons as rate varying Poisson processes with
a base-line firing rate plus rate modulations driven by the LFP fluctuations. Note that in this study we refer to the LFP as **common rate fluctuations of the input signal** (or short: common input). In order to prevent any misunderstanding, we would like to point out that this meaning of "common input” differs from the usual physiological meaning of common input which implies that two neurons receive the same synaptic input due to a bifurcating axon!

In this study we will determine the coherence between different signals present in the model, as shown in Fig. 1. First, we will concentrate on the Poisson model and derive an expression for the coherence between the common input (LFP) and the response of a single Poisson neuron (small circle in Fig. 1). After deriving a similar expression for multi-unit activity, we will compare both results of Spike-Field coherence functions. We will finish the theoretical part, concerning the coherence functions, by deriving expressions for the Spike-Spike coherences, first between two single-unit activities and later also between two multi-unit series of Poisson neurons. Simulation results of these coherence measures will complete the Poisson model section. We will continue by simulations of the complete model, including the conductance-based neurons (large circles in Fig. 1). The common input (LFP) to the Poisson neurons will be taken as the local field potential in order to determine the Spike-Field coherences between the common input and the response(s) of the conductance-based neuron(s). The Spike-Spike coherences are taken between the responses of two conductance-based neurons (single-units) and afterwards also between the sums of ten responses (multi-units) of this neuron type. We will finish with the coherence analysis of experimental data.
2.1 Poisson Model and Coherences

In the simple model (Fig. 1) we feed Poisson neurons with partially common input $N_c \sigma \eta_0(t)$ and uncorrelated noise $(1 - N_c) \sigma \eta_i(t)$ (as described below), in order to translate the local field potential into a series of (partially) correlated spike trains. For this part of the model, we will derive analytical expressions for the coherence between LFP and single or multi-unit activity and for the coherence between spike trains. The spike output of the Poisson neurons is fed into a set of neurons, which could be conductance-based leaky integrate-and-fire neurons, or conductance-based Hodgkin-Huxley neurons.

The Poisson neurons each receive an input

$$x_i(t) = \lambda + N_c \sigma \eta_0(t) + (1 - N_c) \sigma \eta_i(t)$$

(1)

with a constant input $\lambda$, Gaussian colored noise $\eta_0$, and Gaussian white noise $\eta_i$, with $<\eta_i(t)\eta_j(t+\tau)> = \delta_{ij}(\tau)$. The common input ratio $N_c$ varies from zero (uncorrelated input to all neurons) to one (the same input to all neurons). Both $\eta_0(t)$ and $\eta_i(t)$ have zero mean and a variance of one. In this study, $\sigma$ is set to $\lambda/3$ so, that the total input to the neurons is always positive and, therefore, the probability that a spike occurs, too.

Experiments in visual cortex (Fries et al., 2001a, 2001b and 2002) have shown that the local field potential, which represents a measure of the local correlated input to a group of neurons (Buzsáki et al., 2004), has a peak in the power spectrum in the range between 40 and 60 Hz. Therefore, we used bandpass-filtered Gaussian white noise $\eta_0(t)$ as a time-dependent common input, which was obtained by filtering Gaussian white noise with a bandpass filter with 3 dB points at 45 and 55 Hz and a quality factor $Q$ of 5.

The response of Poisson neuron $i$ to the input $x_i(t)$ is represented by a
sequence of action potentials $y_i(t) = \sum_j \delta(t - t^i_j)$, where $t^i_j$ represents the occurrence time of the $j^{th}$ spike of neuron $i$. In this study, we will introduce a discretization of time in bins $\Delta t$ of 1 ms, such that $y_i(t) = 1$ for an action potential in the time interval $[t, t + \Delta t)$ with probability $x_i(t) \Delta t$ and with $y_i(t) = 0$ with probability $(1 - x_i(t) \Delta t)$. Multi-unit activity is defined as the sum of $m$ single-unit activities $z(t) = \sum_{i=1}^{m} \sum_j \delta(t - t^i_j)$.

A commonly used measure to estimate the relation between input $x(t)$ and output $y(t)$ of a neuron is the normalized cross covariance function or correlation coefficient function, which is defined by (Marmarelis and Marmarelis, 1978)

$$\rho_{xy}(\tau) \equiv \frac{C_{xy}(\tau)}{\sqrt{C_{xx}(0) C_{yy}(0)}}$$

with the cross covariance function between two ergodic signals $x$ and $y$ defined as

$$C_{xy}(\tau) = \int \int x(t + \tau) y(t) p(x(t + \tau), y(t)) \ dx(t + \tau) \ dy(t) - \bar{x} \bar{y}$$

where $p(x(t + \tau), y(t))$ is the joint probability distribution of $x(t + \tau)$ and $y(t)$ and where $\bar{x}$ and $\bar{y}$ represent the averaged value of signal $x$ and $y$, respectively.

The coherence function $\gamma(\omega)$ reflects how much of the variations in the output $y$ can be attributed to a linear filtering of the input signal $x$. The coherence function $\gamma(\omega)$ is defined by:

$$| \gamma(\omega) | = \frac{| C_{xy}(\omega) |}{\sqrt{| C_{xx}(\omega) | | C_{yy}(\omega) |}}$$

The coherence takes values in the range between 0 (input and output are fully uncorrelated) and 1 (the output is equal to the input after convolution by a linear system).
First, we will determine the coherence between single-unit activity of a Poisson neuron and the common input by deriving expressions for the covariance functions in the denominator and the cross covariance function in the nominator of Eq. 4.

Consider \( x(t) \) to be the input given by equation 1 and \( y_i(t) = y(t) \) the response of a single Poisson neuron. Each Poisson neuron is represented by a small circle in Fig. 1. The covariance function of the input is given by:

\[
C_{xx}(\tau) = \int \int x(t) x(t + \tau) p(x(t), x(t + \tau)) dx(t) dx(t + \tau)
\]

\[
= \int \int \int x(t) x(t + \tau) p(\eta_0(t), \eta_0(t + \tau)) p(\eta_i(t), \eta_i(t + \tau))
\]

\[
d\eta_0(t) d\eta_0(t + \tau) d\eta_i(t) d\eta_i(t + \tau) - \bar{x}^2
\]

\[
= N_c^2 \sigma^2 \rho(\tau) + (1 - N_c)^2 \sigma^2 \delta(\tau)
\]  

(5)

where the joint probability distributions for \( \tau \neq 0 \) are given by

\[
p(\eta_0(t + \tau), \eta_0(t)) = \frac{1}{2\pi \sqrt{1 - \rho^2(\tau)}} \exp\left(-\frac{\eta_0^2(t + \tau) - 2\rho(\tau)\eta_0(t + \tau)\eta_0(t) + \eta_0^2(t)}{2(1 - \rho^2(\tau))}\right)
\]

\[
p(\eta_i(t + \tau), \eta_i(t)) = p(\eta_i(t)) p(\eta_i(t + \tau))
\]  

(6)

with \( \rho(\tau) = \rho_{\text{norm}}(\tau) \) being the normalized covariance function of the Gaussian colored noise \( \eta_0 \). In order to obtain Eq. 5 we used for the common input colored noise \( \eta_0(t) \) and for the uncorrelated noise \( \eta_i(t) \) in the input signal \( x(t) \) defined in Eq. 1 for \( \tau = 0 \)

\[
\int \eta_0(t + \tau) p(\eta_0(t + \tau), \eta_0(t) | \tau) d\eta_0(t + \tau) = \eta_0(t) p(\eta_0(t))
\]

\[
= \frac{\eta_0(t)}{\sqrt{2\pi}} \exp\left(-\frac{\eta_0^2(t)}{2}\right)
\]
The first term at the r.h.s. of Eq. 5 is due to the common input to the neurons, the second term due to the neuron specific input fluctuations.

The covariance function of a single-unit response results in:

\[ C_{yy}(\tau) = p(y(t + \tau) = 1, y(t) = 1) - \overline{y}^2 \]

\[ = \int \int \int p(y(t + \tau) = 1 \mid \eta_0(t + \tau), \eta_i(t + \tau)) \ p(y(t) = 1 \mid \eta_0(t), \eta_i(t)) \]

\[ p(\eta_0(t), \eta_0(t + \tau)) \ p(\eta_i(t), \eta_i(t + \tau)) \ d\eta_0(t) d\eta_0(t + \tau) d\eta_i(t) d\eta_i(t + \tau) - \overline{y}^2 \]

\[ = \Delta t^2 \sigma^2 N^2_c (\rho(\tau) - \delta(\tau)) + \Delta t \lambda (1 - \Delta t \lambda) \delta(\tau) \tag{8} \]

where \( \rho \) is the normalized covariance function of the Gaussian colored noise.

The cross covariance function between the input \( x \) and the single-unit response \( y \) is given by

\[ C_{xy}(\tau) = \int x(t + \tau) p(x(t + \tau), y(t) = 1 \mid \tau) \ dx(t + \tau) - \overline{x} \overline{y} \]

\[ = \Delta t \sigma^2 N^2_c \rho(\tau) + \Delta t \sigma^2 (1 - N_c)^2 \delta(\tau) \tag{9} \]

The first term at the r.h.s. is due to the common input, the second term due to the neuron specific input fluctuations.

The local field potential is considered to be a measure of the local common input of the neurons near the recording electrode. Therefore, we will take only the contributions of the common input in Eqs. 5 and 9 into account for determining an analytical expression for the Spike-Field coherence between single-unit activity and local field potential. The Spike-Field coherence between the single-unit activity and the common input can be obtained by
taking the Fourier transform of Eq. 8 and the first terms at the r.h.s. of Eqs. 5 and 9. This results in:

\[
| \gamma_{SU}^{\rho} \rho(\omega) | = \frac{\Delta t \sigma^2 N_c^2 | \rho(\omega) |}{\sigma N_c \sqrt{\rho(\omega)}} | \Delta t \lambda (1 - \Delta t \lambda) + (\Delta t \sigma)^2 N_c^2 (\rho(\omega) - 1) |
\]

\[
= \frac{\Delta t \sigma N_c \sqrt{\rho(\omega)}}{\sqrt{\Delta t \lambda (1 - \Delta t \lambda) + (\Delta t \sigma)^2 N_c^2 (\rho(\omega) - 1) }}</mbox\>

\[
\approx \frac{\Delta t \sigma N_c \sqrt{\rho(\omega)}}{\sqrt{\Delta t \lambda}} (10)
\]

where \( \rho(\omega) \) is the Fourier transform of the normalized covariance function of the colored noise. The approximation in the last step is valid since \((\Delta t \sigma)^2 \ll \Delta t \lambda\).

In order to obtain an expression for the coherence between multi-unit activity and the common input, we have to determine the covariance function of multi-unit activity and the cross covariance function between multi-unit activity and common input. Since the probability that a neuron fires twice within a time bin \( \Delta t \) is very small \( ((\Delta t \lambda)^2 \ll 1) \), we only take terms up till the second order of \( \Delta t \) into account. For multi-unit activity \( z \), which is the summation over \( m \) simultaneously recorded single-unit signals \( y_i(t) \) with a common input ratio \( N_c \) and for \( m \ll \frac{1}{\Delta t \lambda} \), we find for the multi-unit covariance function:

\[
C_{zz}(\tau) = \sum_{j=0}^{m} \sum_{k=0}^{m} p(z(t + \tau) = j, z(t) = k) - z^2
\]

\[
\approx m (\Delta t)^2 \sigma^2 N_c^2 (m \rho(\tau) - \delta(\tau)) + m \Delta t \lambda (1 - \Delta t \lambda) \delta(\tau) (11)
\]

The cross covariance function between multi-unit activity and the total
input is given by:

\[ C_{zz}(\tau) = \sum_{j=0}^{m} \int x(t + \tau) \, p(x(t + \tau), z(t) = j) \, dx(t + \tau) - \overline{x} \overline{z} \]

\[ \approx m \Delta t \sigma^2 N_c^2 \rho(\tau) + m \Delta t \sigma^2 (1 - N_c)^2 \delta(\tau) \]  

(12)

Eq. 12 is equal to Eq. 9 except for the factor \( m \).

Combining equation Eq. 11 and the first term at the r.h.s. of Eqs. 5 and 12 leads to the expression for the Spike-Field coherence between multi-unit activity and the common input:

\[ \left| \gamma_{MU}^{SpF}(\omega) \right| \equiv \frac{|C_{zx}(\omega)|}{\sqrt{|C_{xx}(\omega)|} \sqrt{|C_{zz}(\omega)|}} \]

\[ \approx \frac{\Delta t \sigma N_c \sqrt{|mp(\omega)|}}{\sqrt{\Delta t \lambda (1 - \Delta t \lambda) + (\Delta t \sigma)^2 N_c^2 (mp(\omega) - 1)}} \]

\[ \approx \frac{\Delta t \sigma N_c}{\sqrt{\Delta t \lambda}} \sqrt{|mp(\omega)|} \]  

(13)

The Spike-Field coherence for multi-unit activity, which is the summation of \( m \) single-unit recordings, is equal to that for single-unit activity (Eq. 10) except for a coefficient \( \sqrt{m} \).

We can also calculate the coherence between two single-unit responses or between two multi-unit recordings. The cross covariance function between two single-unit signals \( y_1 \) and \( y_2 \) is given by:

\[ C_{y_1y_2}(\tau) = p(y_1(t + \tau) = 1, y_2(t) = 1) - \overline{y_1} \overline{y_2} \]

\[ = (\Delta t \sigma)^2 N_c^2 \rho(\tau) \]  

(14)

The Spike-Spike coherence between two simultaneously recorded single-unit
signals with partly common input is given by:

\[ \left| \gamma_{SU}^{\text{SI}} \right| = \frac{|C_{y_1y_2}(\omega)|}{|C_{yy}(\omega)|} \]

where we used \( C_{yy} = C_{y_1y_1} = C_{y_2y_2} \).

The cross covariance function of two multi-unit signals is given by:

\[ C_{z_1z_2}(\tau) = \sum_{j,k=0}^{m} j k p(z_1(t+\tau) = j, z_2(t) = k | \tau) - \bar{z}^2 \]

\[ \approx m^2 N_c^2 (\Delta t \sigma)^2 \rho(\tau) \]  

(16)

The Spike-Spike coherence between two simultaneously recorded multi-unit signals is given by:

\[ \left| \gamma_{SpSp}^{\text{MU}} \right| = \frac{m^2 (\Delta t \sigma)^2 N_c^2 |\rho(\omega)|}{|m^2 (\Delta t \sigma)^2 N_c^2 \rho(\omega) + m (\Delta t \lambda (1 - \Delta t \lambda) - (\Delta t \sigma)^2 N_c^2)|} \]

\[ \approx \frac{(\Delta t \sigma N_c)^2}{\Delta t \lambda} \frac{|\rho(\omega)|}{m} \]

(17)

Equations 15 and 17 show that for low firing rates (\( \lambda \Delta t << 1 \)) and for \( m << 1/(\lambda \Delta t) \) the expected Spike-Spike coherence between multi-unit signals is approximately \( m \)-times larger than the expected Spike-Spike coherence between single-unit signals. Equations 13 and 17 show that the Spike-Spike coherence is (approximately) the square of the Spike-Field coherence and thus much smaller.
In summary, for our Poisson model, the Spike-Field coherence and the Spike-Spike coherence are larger for multi-unit recordings than for single-unit recordings and the Spike-Spike coherences are much smaller than the Spike-Field coherences.

2.2 Conductance-based LIF Model

Since the simple Poisson model is not very realistic, we will discuss a model where conductance-based leaky integrate-and-fire neurons (LIF) receive spike input from the Poisson neurons. The membrane equation of the neurons is then given by

$$C \frac{dU}{dt} = -I_e(t) - I_l(t)$$

(18)

with membrane capacitance $C$, membrane potential $U$ and excitatory and leak currents $I_e$ and $I_l$, respectively. These currents are given by

$$I_e(t) = G_e(t)(U(t) - E_e)$$

$$I_l(t) = G_l(U(t) - E_r)$$

(19)

with the excitatory reversal potential $E_e$, rest potential $E_r$ and excitatory (leak) conductance $G_e(t)$ ($G_l$). The excitatory conductance depends on the recent pre-synaptic spike-times and is modelled by:

$$G_e(t) = \sum_{i=1}^{m} \sum_{k=1}^{k_{max}} g_e(t - t_{ik}^e)$$

(20)

with $t_{ik}^e$ the time of the $k^{th}$ spike of neuron $i$ and with $m$ the number of input neurons. In this study, the conductivity is modelled by an alpha function:

$$g_e(t) = g_0 \left( \frac{t}{\tau_e} \right) \exp \left( -\frac{t}{\tau_e} \right) \Theta(t)$$

(21)
Here $\tau_e$ denotes the time-to-peak of the conductivity $g_e(t)$. $\Theta$ is the Heaviside function. When the membrane potential reaches the threshold $U_{thr}$, a spike will be generated and the membrane potential $U$ is reset. Specific values for the LIF model are (Stroeve and Gielen, 2001): membrane capacitance $C = 325$ pF, threshold potential $U_{thr} = -55$ mV, excitatory reversal potential $E_e = 0$ mV, rest potential $E_r = -75$ mV, leak conductance $G_l = 25$ nS, $g_0 = 3.24$ nS and $\tau_e = 1.5$ ms.

Each LIF neuron (large circle in Fig.1) receives input from a population of 100 Poisson neurons (oval), with a spike-rate output modulated by a common input $(\lambda + N_c \sigma \eta_0(t))$ and an uncorrelated input $((1 - N_c) \lambda + \sigma \eta(t))$, where $\eta_0(t)$ is Gaussian colored noise and $\eta(t)$ is Gaussian white noise, both with zero mean and variance one. For our simulations, these quantities are chosen as for the Poisson model except for $\sigma$, which has been chosen by $\sigma = 20/12$, for $\lambda = 20$. In our simulations, we derived the membrane potential by using Euler Integration with a step width of 1 ms.

### 2.3 Conductance-based Hodgkin-Huxley Model

The next modification of our simple model (Fig.1) is the replacement of the conductance-based LIF-neurons (circles) by conductance-based Hodgkin-Huxley neurons. These neurons are characterized by the differential equation:

$$ C \frac{dU}{dt} = -I_{Na}(t) - I_K(t) - I_l(t) - I_e(t) \quad (22) $$

where the sodium and potassium currents are given by:

$$ I_{Na}(t) = g_{Na}m^3h(U(t) - V_{Na}) $$

$$ I_K(t) = g_Kn^4(U(t) - V_K) \quad (23) $$

16
and the leak and excitatory currents as described before (see Eq. 19). \( V_{Na} \) and \( V_K \) are the sodium and potassium reversal potentials. The time-varying gate variables \( m, h \) and \( n \) are given by the differential equation

\[
\frac{dx}{dt} = \frac{x_{\infty} - x}{\tau_x}
\]

with \( x \{ m, h, n \}, \tau_x = \frac{1}{\alpha_x + \beta_x} \) and \( x_{\infty} = \frac{\alpha_x}{\alpha_x + \beta_x} \)

These parameters are expressed by:

\[
\begin{align*}
\alpha_m &= 0.1 \frac{U + 40}{1 - \exp(-0.1(U + 40))} \\
\beta_m &= 4 \exp(-(U + 65)/18) \\
\alpha_n &= \frac{0.01(U + 55)}{1 - \exp(0.1(U + 55))} \\
\beta_n &= 0.125 \exp(-(U + 65)/80) \\
\alpha_h &= 0.07 \exp(-(U + 65)/20) \\
\beta_h &= \frac{1}{1 + \exp(-0.1(U + 35))}
\end{align*}
\]

The typical values of the parameters at 6.3°C for the squid axon are: membrane capacitance per unit surface \( C = 1 \mu F/cm^2 \), maximum conductance per unit area for the sodium, potassium and leak currents, \( g_{Na} = 120 \, mS/cm^2 \), \( g_K = 36 \, mS/cm^2 \), \( G_l = 0.3 \, mS/cm^2 \), excitatory reversal potential \( E_e = 0 \) mV, rest potential \( E_r = -75 \) mV, sodium reversal potential \( V_{Na} = 50 \) mV, potassium reversal potential \( V_K = -77 \) mV, \( g_0 = 1.5 \, \mu S/cm^2 \) and \( \tau_e = 1.5 \) ms.

Like for the conductance-based LIF model, we use spike trains as input for the conductance-based HH neurons. We derived the membrane potential using Euler Integration with a step width of 0.05 ms for the HH-neurons. The sequence of output action potentials of the HH model was represented in time bins of 1 ms.
2.4 Multitaper Method

The usual way of estimating the frequency content of a signal is by taking the Fourier spectrum (periodogram). If the signal $x(t)$ has a stochastic character, the variance of the spectral estimates in the Fourier transformed signal may be considerable. This is particularly important if we are dealing with the coherence of two stochastic spike series. This is not solved by taking a signal with a longer duration since a longer time signal gives rise to a higher spectral resolution in the Fourier transformed signal, but does not decrease the variance of each point in the frequency spectrum.

To solve this problem, the multitaper estimation procedure was introduced (see Thomson, 1982; Mitra and Pesaran, 1999). The key idea behind the Welch method and the multitaper method is that a physiological signal has no discontinuities in the frequency spectrum and that the variability in the estimate of a signal can be reduced by smoothing in the frequency domain. The multitaper method achieves this by optimizing the minimum of bias and variance of the estimate. This involves the use of multiple orthonormal data tapers, which provide a local eigenbasis in frequency space for finite length data sequences. A simple example of the method is given by the direct multitaper spectral estimate $S_{MT}(f)$ of a discrete time series signal $x_t$ with $t = n\Delta t$ and $n \in 1, 2, \ldots, N$ defined as the average over individual tapered spectral estimates,

$$S_{MT}(f) = \frac{1}{N} \sum_{k=1}^{K} |\hat{x}_k(f)|^2$$  \hspace{1cm} (26)

where

$$\hat{x}_k(f) = \sum_{1}^{N} w_k(k)x_t exp(-2\pi i ft)$$ \hspace{1cm} (27)
Here $w_t(k)$ $(k = 1, 2, \ldots, K)$ are $K$ orthogonal taper functions with appropriate properties. Let $w_k(k, W, N)$ be the $k$-th taper of length $N$ and frequency bandwidth parameter $W$. This forms an orthogonal basis set for sequences of length $N$, characterized by a bandwidth $W$. The important feature of these sequences is that for a given bandwidth parameter $W$ and taper length $N$, $K=2NW-1$ sequences out of a total of $N$ each have their energy effectively concentrated within a range $2W$ in frequency space. This range can be shifted from $[-W, W]$ centered around zero frequency to any nonzero center frequency interval $[f_0 - W, f_0 + W]$ by simply multiplying by the appropriate phase factor $\exp(2\pi f_0 t)$. The product of the number $N$ of samples in the signal and the bandwidth $W$ of the spectral estimator (NW) is used to balance between variance and resolution of the power spectral density estimation. In this article, we use a simple set of orthonormal sine tapers $\{\omega_{t,k} : t = 1, \ldots, N; k = 0, \ldots, N - 1\}$ (McCoy et al., 1997). The $k$-th taper is given by:

$$\omega_{t,k} = \sqrt{\frac{1}{N + 1}} \sin \left( \frac{(k + 1)\pi t}{N + 1} \right)$$ (28)

For our analysis, we used signals of length 0.512 s and the first $K = 2NW - 1$ tapers, which gave $K = 6$. This means that the bandwidth $W$ of the spectral estimator is 6.83 Hz. The frequency binwidth is $f_s/nfft = 1.95$ Hz, with sampling frequency $f_s$ (1000 Hz) and where $nfft$ is the number of data in the FFT (512).

### 2.5 Neurophysiology

#### 2.5.1 Surgery

Experiments were performed on two male Macaca mulatta, weighting 8-11 kg. Each monkey was surgically implanted with a head post, a scleral eye coil, and
a recordings chamber. Surgery was conducted under aseptic conditions with isofluorane anesthesia. Antibiotics and analgesics were administered after the operation. The skull remained intact during the surgery. Subsequently, small holes (5 mm in diameter) were drilled within the recording chamber under ketamine anesthesia and xylazine analgesic. All experimental procedures were performed in accordance with the National Institute of Health guidelines and approved by the National Institute of Mental Health Intramural Animal Care and Use Committee.

2.5.2 Recording technique

Neuronal recordings were made through the surgically implanted chamber overlying area V4. Recordings were made from two hemispheres in two monkeys. Four to eight tungsten microelectrodes (Frederick Haer and Co., Brunswick, ME) were inserted through the intact dura mater by means of a hydraulic microdrive (Frederick Haer) mounted to the recording chamber. The electrodes had tip impedances of one to two MΩ and were separated by 650 or 900 mm. Each electrode was advanced separately at a very slow rate (1.5 mm/s) to minimize suppression artifacts (dimpling) resulting from the deformation of the cortical surface by the electrode. Data amplification, filtering and acquisition was done with a Multichannel Acquisition Processor (MAP) system from Plexon Incorporated (Dallas, TX). The signal from each electrode was passed through a headstage with unit gain and an output impedance of 240 Ω. It was then split to separately extract the spike and the LFP components. For spike recordings, the signals were filtered with a passband of 100 - 8000 Hz, further amplified and digitized with 40 kHz. A threshold was set interactively and spike waveforms were stored for a time window from 150 μs before to 700 μs after threshold crossing. The threshold clearly separated spikes from noise,
but was chosen to include multi-unit activity. Offline, we performed a principal component analysis of the waveforms and plotted the first against the second principal component. Those waveforms that corresponded to artifacts were excluded. For multi-unit analyses, all other waveforms were accepted. For single-unit analyses, only clearly isolated clusters of high-amplitude spikes were accepted. For all further analyses involving spikes, only the times of threshold crossing were kept and downsampled to 1 kHz. For LFP recordings, the signals were filtered with a passband of 0.7-170 Hz, further amplified and digitized at 1 kHz.

Each electrode was lowered separately until it recorded visually driven activity. Once this had been achieved for all electrodes, we fine-tuned the electrode positions to optimize the signal-to-noise ratio of the multiple spike recordings and to obtain as many isolated single-units as possible. Since the penetration was halted as soon as clear visually driven activity was obtained, most of the recordings were presumably done from the superficial layers of the cortex.

2.5.3 Behavioral paradigm and visual stimulation

Stimuli were presented on a 17 inch CRT monitor 0.57 m from the monkeys eyes that had a resolution of 800*600 pixel and a screen refresh rate of 120 Hz non-interlaced. Stimulus generation and behavioral control were accomplished with the CORTEX software package (http://www.cortex.salk.edu/). A trial started when the monkey touched a bar mounted in front of him and 250 ms later, a fixation point appeared at the center of the screen. When the monkey brought his gaze within 0.7° of the fixation spot for at least 1000 ms, stimulus presentation commenced. The task of the monkey was to fixate the fixation target while a drifting sine wave grating was presented within the receptive field. He had to release the bar between 150 and 650 ms after a
change in stimulus color of the sine-wave grating. That change in stimulus color could occur at an unpredictable moment in time between 500 and 5000 ms after stimulus onset. With this task, we assured that the monkey was constantly monitoring the grating that induced the recorded neuronal activity while fixating the fixation target. The first 300 ms after stimulus-onset were discarded in order to avoid strong stimulus onset related transients and the rest of the data were analyzed until the time of the color change. Successful trial completion was rewarded with four drops of diluted apple juice. If the monkey released the bar too early or if he moved his gaze out of the fixation window, the trial was immediately aborted and followed by a timeout.

3 Results

In this section we will describe coherence estimates between various signals. We always first analyze the Spike-Field coherence followed by the Spike-Spike coherence, for both single-unit and multi-unit activity. The simulation results will be shown first for the Poisson model neurons (small circles in Fig. 1), followed by the conductance-based neurons (LIF and HH; big circles in Fig. 1). We will end this section with the results of the Spike-Field and Spike-Spike coherences of experimental data. Finally we compare an analysis without and with the use of multitaper techniques.

3.1 Simulation results of the Poisson model

The top panels of Fig. 2 show the predicted (dashed line) and the simulated (solid line) coherence between the LFP and single-unit activity (Fig. 2A) and between LFP and multi-unit activity (Fig. 2B) for the Poisson neurons. In both cases, there is a good match between the simulated and predicted Spike-
Field coherence functions.

The "predicted" coherence functions were obtained using the Fourier transform of the normalized covariance function \( \rho(\tau) \) of the LFP. Since the LFP had a finite duration, \( \rho(\omega) \) has noisy fluctuations which are evident in the "predicted" coherence function of Fig. 2. The coherence is larger for the multi-unit activity (Fig. 2B) than for the single-unit activity (Fig. 2A). The ratio between the peak coherence for multi-unit versus single-unit activity (0.37/0.12 = 3.08) is in agreement with the square root of the number of neurons (\( \sqrt{10} = 3.16 \)) that contributes to the multi-unit activity (see Eqs. 10 and 13). One could argue that the larger coherence for the multi-unit case could be due to the fact that the multi-unit recording with ten (simultaneously measured) single-unit signals contains ten times more action potentials. In order to correct for this, the single-unit signal in our simulations was ten times longer than the multi-unit signal such that the number of action potentials was the same in both signals.

Figure 2C shows the simulated (solid line) and predicted (dashed line) Spike-Spike coherence for single-unit activity for the Poisson neurons. Figure 2D shows the same results for multi-unit activity. The simulated and predicted coherence are in agreement for the single-unit and multi-unit data.

The Spike-Spike coherence for multi-unit activity increases linearly with the number of units \( (m = 10) \) in the multi-unit recording for the Spike-Spike coherence as long as \( m << 1/(\lambda \Delta t) \). This is shown by the peaks of the coherences in Figs. 2C and 2D (0.015 vs. 0.14).

The Spike-Spike coherence differs from the Spike-Field coherence in two aspects (see equations 17 and 13). The first difference concerns the factor \( m \) versus \( \sqrt{m} \) for Spike-Spike versus Spike-Field coherence. The second difference is that the Spike-Field coherence is proportional to \( \sqrt{\rho(\omega)} \), whereas the Spike-
Spike coherence is proportional to the normalized covariance function of the common input, $\rho(\omega)$. Since $0 < |\rho(\omega)| < 1$, $\rho(\omega)$ is smaller and more narrow than $\sqrt{\rho(\omega)}$.

Both aspects are reproduced in Fig. 2. The peak value of the Spike-Spike coherence (fig. 2D: 0.14) is approximately the square root of the maximum peak value of the Spike-Field coherence (fig. 2B: 0.37).

Equations 10, 13, 15 and 17 for the Spike-Field and Spike-Spike coherence do not depend on the duration of the LFP and spike series. Therefore, the expectation value for the coherence functions will not change if the duration of the single-unit recordings increases. The only effect of a longer duration of the spike recording is a reduction of the noise in the coherence function. Therefore, a smaller coherence for single-unit recording relative to multi-unit recording cannot be compensated by a longer recording time for the single-unit recordings.

### 3.2 Simulation results for the conductance-based LIF and HH model

Figure 3 shows the Spike-Field and the Spike-Spike coherences for single-unit and multi-unit recordings for the conductance-based LIF-neuron (dashed-dotted line), the conductance-based HH-neuron (dashed line) model and the predictions for the Poisson model (solid line) according to Eqs. 10, 13, 15 and 17, all with $\sigma = 20/12$. The parameters were chosen in such a way that the mean firing rate was the same for the Poisson neuron, the LIF and the HH-neurons. Figure 3A (3B) shows the coherence between the LFP and single-unit (multi-unit) activity. Both, for the single- and multi-unit recordings, the Spike-Field coherence estimate shows a significant peak near 50 Hz.
The peak value of the Spike-Field coherence estimates for multi-unit recording (Fig. 3B) is considerably higher than the peak value for the single-unit recording (Fig. 3A). The Spike-Field coherence estimates for the LIF and HH network have much higher values than the Spike-Field estimates of the Poisson network. The ratio of the two peak Spike-Field coherence values (multi-unit/single-unit) is smaller than the square root of the number \( m \) (\( m = 10; \sqrt{m} = 3.16 \)) of neurons active in the multi-unit.

Figure 3C (3D) shows the coherence between two single-unit (multi-unit) recordings. For the single-unit recordings, no significant peak near 50 Hz is visible. The predicted coherence for the Poisson model is small and lies almost on the x-axis, with a small (hardly visible) peak near 50 Hz for the multi-unit activity. For multi-unit activity (Fig. 3D), a significant peak near 50 Hz is visible.

The peak coherence is larger for the LIF neuron and the HH model than for the Poisson neuron, both for the Spike-Field coherence as well as for the Spike-Spike coherence. The question is whether the higher coherence values for the LIF and HH neuron are due to the dynamics of these neurons or due to the different type of input (continuous LFP-signal for the Poisson neurons versus spike input to the LIF and HH neuron). In order to investigate this, we have calculated the coherence between the spike input to the LIF and HH neuron (i.e. the sum of spike series of the Poisson neurons) and their output. These coherence values are much higher than the coherence between the input and the output of a Poisson neuron, with the same input as the LIF and HH neuron. Therefore, we conclude that the higher coherence values of the LIF and HH neuron are the result of the dynamic properties of those neuron types.
3.3 Data from monkey visual cortex

As a final test of the significance of the model simulations, we have analyzed data obtained in monkey visual cortex (Fries et al., 2001b). The data consisted of single- and multi-unit activity and local field potential activity recorded simultaneously in area V4 of the awake macaque monkey.

Figure 4A shows the coherence between the measured LFP and the single-unit signal, which contains 15,371 spikes. The dashed-dotted lines indicate the 95% confidence levels of the coherence estimates, calculated with 130 bootstraps, the solid line is the average of the bootstrap replications. For a multi-unit recording with a similar number (\( n = 16,031 \)) of spikes and thus a shorter duration, the Spike-Field coherence is shown in Fig. 4B. In both Fig. 4A and 4B, there is a peak in Spike-Field coherence near 50 Hz. For multi-unit activity (sum of approximately eight single-unit activities), this peak is significantly higher than that for single-unit activity. Fig. 4C shows the Spike-Field coherence for a multi-unit signal with a duration equal to the duration of the single-unit recording used for Fig. 4A. The coherence estimate, including the 95% confidence level, in Fig. 4C is entirely within the 95% regime shown in Fig. 4B. Figs. 4B and C illustrate that increasing the duration of a spike recording improves the signal-to-noise ratio but does not change the expectation value of the coherence function.

The Spike-Spike coherence for single-unit signals (Fig. 4D) does not show a significant peak near 50 Hz. Neither does the Spike-Spike coherence for multi-unit signals, if the analyzed time period is shortened such that the number of spikes is the same as in the longer single-unit recording (Fig. 4E). The coherence values for the multi-unit signals in Fig. 4E are larger than for single-unit signals, shown in Fig. 4D. However, the 95% confidence regime is relatively large. Fig. 4F shows the Spike-Spike coherence for multi-unit
signals with duration equal to the duration of the single-unit activities used in Fig. 4D. The coherence function in Fig. 4F shows a significant peak near 50 Hz. The signal-to-noise ratio is considerably better than in Fig. 4E. The results shown in Fig. 4 are typical for the spike signals that were obtained in the study by Fries et al. (2001b).

All coherence estimates of Fig. 4 were obtained with the multitaper method as described in the Methods and Theory section. Each trial was cut into equally long segments of 512 ms such that the number of tapers was constant. In fact this is a combination of the Welch method and the multitaper technique.

As an alternative to using the Welch method with equally long time segments, one could use the multitaper technique for the analysis of spike signals, which in general each have a different duration. Since the trial durations are different, so is the number of samples in each trial. In order to keep the frequency of smoothing in the frequency domain (2W) constant, the number of tapers given by \( K = 2NW - 1 \), is different for each trial. Since averaging over power spectra of different trials requires that the frequency resolution of the spectra should be the same for all trials, all signals (after application of the tapers) are made of equal duration by adding zeros (zero padding). Now the average FFTs of the cross and covariance functions can be derived for the coherence functions.

Figure 5A shows the Spike-Spike coherence estimate of experimental multi-unit spike trains without the use of multitapers and without using the Welch method. The frequency resolution in Fig. 5 is much higher than that in Fig. 4F, because the number of data points in the frequency domain is eight times larger. The variance in the coherence estimate is large and no significant
peak is visible near 50 hz. By applying the multitaper method with \( W = 5 \) HZ, the variance is reduced and a significant peak near 50 Hz is visible in the same data (see Fig. 5B).

4 Discussion

The coherence between neuronal signals (e.g. EEG, MEG, two spike trains) or between neuronal input (e.g. a local field potential) and neuronal output is generally considered as an important measure for synchronization or temporal locking. The main result of this study is that the coherence reaches higher values when multi-unit spike activity is used instead of single-unit activity. This cannot be overcome by extending the recording time of the single-unit signal. The latter only improves the signal-to-noise ratio (SNR) of the coherence. The SNR can also be improved by using multitaper techniques or by using the Welch-method. Experimental data obtained in monkey V4 could be reproduced by simulations. Our results illustrate the significance of multi-unit activity over single-unit activity, and provides new insights for the interpretation of multi-unit activity and for the interpretation of coherence estimates using oscillatory activity such as \( \beta \) and \( \gamma \)-oscillations, in neuroimaging studies. Our results will be discussed in more detail below.

Although many studies have investigated the firing behavior of Poisson neurons and Integrate-and-Fire neurons for partially correlated and uncorrelated input (for an overview, see Salinas and Sejnowski, 2001), most studies have focussed on the mean firing rate and the coefficient of variation (see e.g. Feng and Brown, 2000; Stroeve and Gielen, 2001; Salinas and Sejnowski, 2000,
2002; Kuhn et al., 2004). The coefficient of variation is an important parameter to understand the temporal structure of spike trains, but this parameter itself cannot provide insight in the temporal correlation of the action potential signals of different neurons receiving partially correlated input. As far as we know, the present study is the first to give analytical expressions and results of computer simulations for the coherence between local-field potential and neuronal firing and for the coherence between spike signals for neurons receiving (partly) correlated input.

In this study, we investigated the relations between Spike-Field and Spike-Spike coherences for single-unit and multi-unit activity. Analytical expressions (Eqs. 10, 13, 15 and 17) showed that the Spike-Field coherence values are higher than the Spike-Spike coherence values and that the coherences are larger for multi-unit recordings than for single-unit recordings. Although we could only derive analytical expressions for the coherence between input and spike output for the Poisson neurons, simulations show qualitatively similar results for an ensemble of conductance-based LIF neurons or HH neurons.

For Poisson neurons, the Spike-Spike coherence should be proportional to the square of the Spike-Field coherence. This was confirmed by simulations (compare Figs. 2B and 2D) where the spike-spike coherence equals the square of the spike-field coherence for the Poisson model. Figs. 3A, 3B and 3D show similar results for the conductance-based LIF model and for the Hodgkin-Huxley neuron model. The full width at half maximum and the amplitude of the peak are smaller for the Spike-Spike than for the Spike-Field coherence, as expected in case the Spike-Spike coherence is proportional to the square of the Spike-Field coherence, which has values between zero and one. However, coherence values were typically larger for the conductance-based LIF and Hodgkin-Huxley neuron than for the Poisson neuron. This is due to the
characteristic dynamic properties of the neuron models.

Our results demonstrate that multi-unit activity gives significantly higher estimates for the coherence than single-unit activity, even if the number of action potentials in both signals is the same (see Figs. 4A, 4B and 4D, 4E). This is partially due to the fact that the mean firing rate is typically higher in a multi-unit recording than in a single-unit recording and the modulations in firing rate are larger. Eqs. 10 and 13 show that the coherence decreases with the square root of firing rate (proportional to $\lambda$) but increases linearly with modulation depth $\sigma$. Since firing rate and modulation depth increase proportionally when adding single-unit signals, the coherence will effectively increase with the number of single-unit contributions in a multi-unit signal.

Several studies have reported a lack of evidence for synchronized neuronal activity, see e.g. Tovee and Rolls (1992) in the inferior temporal visual cortex and Luck et al. (1997) who did not observe clear synchronization in neuronal responses in V2 and V4. This is in contrast to findings by Fries et al (2001b). Our results indicate that the explanation for these apparently contradictory findings may be related to the techniques used to analyze the neuronal data. In figure 3C the Spike-Spike coherence between single-unit signals is small and disappears in the relatively high variance of the estimate. Simulations with larger values of $\sigma$ (larger modulations of the stimulus) showed a clear, small and narrow peak near 50 Hz. However, the signal-to-noise ratio increases to plausible levels only for unrealistically high modulations of the input. Therefore, the variance in experimental data should be reduced by using dedicated data analysis techniques like the multitaper method (see Figs. 4 and 5).

Our simulations were done for data segments of equal duration (512 ms) and with a constant number ($K=6$) of tapers repeated over many time segments. This results in smoothing of the frequency spectrum.
by averaging over many signals.

In electrophysiological experiments the recording duration will vary in different experiments and will typically be much longer than 512 ms. Therefore, Fries et al. (2001b) used a different number of tapers for each recording signal, such that smoothing was done over the same frequency window ($2W = \text{constant}$) for all experimental data. Since the duration of their recordings was typically much longer than 512 ms, the longer duration gives more samples in the time domain, which results in a higher resolution in the frequency domain. This is illustrated in Fig. 5. Their result shows a higher resolution in the frequency domain but averaging over a smaller number of signals. Effectively the result is the same: the reduction of smoothing by the smaller number of signals is compensated by smoothing by the tapers over a larger number of samples in the frequency domain. However, note that the multitaper method with Slepian sequences as tapers is optimal among quadratic estimators because of the good concentration properties of Slepian sequences (see Percival and Walden, 2002). The lack of optimality of the Welch estimates means that it is a more biased estimate than the multitaper estimate with Slepian sequences, the variance and the frequency resolution being equal. The bias will grow as the size of the windows becomes smaller.

Figure 1: Schematic overview of the network of neurons for the simulations. A set of Poisson neurons receives common input (local-field potential) and uncorrelated input to generate a set of correlated spike trains. These spike trains provide the input for a set of neurons, which are modeled as leaky integrate- and-fire (LIF) neurons or Hodgkin-Huxley (HH) neurons.

A population of Poisson neurons is represented by an oval with small circles. Each Poisson neuron receives a common input given by \( \lambda + N_c \sigma \eta_0(t) \) and an unique input given by \( (1-N_c)\sigma \eta_{ij}(t) \), which is uncorrelated in time and space. \( \lambda \) is a constant, \( \eta_0 \) represents the common input to the Poisson neurons and is represented by band-pass filtered Gaussian white noise, \( \eta_{ij} \) is Gaussian white noise.

noise for the $j^{th}$ Poisson neuron of the $i^{th}$ population.

**Poisson model:** Only one population of 20 Poisson neurons is used for the Poisson model. $y_i(t)$ represents the single-unit activity of Poisson neuron $i$, multi-unit activity is the sum of the responses of ten neurons.

**LIF (HH) model:** Each of the 20 LIF (HH) neuron (large circle) receives input from one of the 20 populations with 100 Poisson neurons each (oval). Single-unit activity is the response of one conductance-based neuron, multi-unit activity is the sum of ten single-unit activities.

Figure 2: Predicted (dashed lines) and simulated (solid lines) coherence functions for LFP and single-unit (A,C) and multi-unit (B,D) signals for the Poisson neurons (see Fig. 1). Parameter values used were $\lambda = 20$, $\sigma = 20/12$, $N_c = 0.4$, and a simulation duration of 512 s. The number of action potentials in the multi- and in the single-unit signals is about 20.480 spikes.

A) The coherence between LFP and single-unit activity. B) The coherence between LFP and multi-unit activity shows a peak near 50 Hz, which is larger than that for single-unit activity shown in A. C) The predicted and simulated coherences between two single-unit activities. D) The predicted and simulated coherence function between two multi-unit activities.

Figure 3: Coherences between LFP and single-/multi-unit activities for the conductance-based LIF model (dashed-dotted lines), the HH model (dashed lines) and the predictions for the Poisson model (solid line) according to Eqs. 10, 13, 15 and 17. Parameter values used were $\lambda = 20$, $\sigma = 20/12$, $N_c = 0.4$, and a simulation duration of 512 s.

Figure 4: Coherences between LFP and single- or multi-unit recordings (experimental data), using the multi taper method.

For the multi taper method we used a set of six orthonormal sine tapers. The 95% confidence level (dashed-dotted lines) is obtained using 130 bootstraps.

A) Coherence between LFP and single-unit recording with 15,371 spikes. B) Coherence between LFP and multi-unit recording, with 16,031 spikes. C) Coherence between LFP and multi-unit recording, with 6,687,666 spikes. D) Coherence between two single-unit recordings. The variance in coherence is too large to detect a significant peak near 50 Hz. E) Coherence between two multi-unit recordings. F) Coherence between two multi-unit recordings, with durations equal to those of the single-unit recordings used in Fig. 4A. Compared to Fig. 4E the 95% confidence regime has been reduced.

Figure 5: The effect of the multitaper method on the Spike-Spike Coherence between multi-units.

Fig. 5A shows the Spike-Spike coherence estimate of experimental data without the use of multitapers. There is no significant peak near 50 Hz. Using the multitaper method with sine-tapers resulted in a significant peak (Fig. 5B) and a significant reduction of the 95% regime.
