Short mucin 6 alleles are associated with *H pylori* infection

**INTRODUCTION**

*H pylori* has the unique ability to colonize the human stomach. Infection with *H pylori* invariably leads to gastritis and in many instances to peptic ulcer disease[1]. Additionally, *H pylori* infection has been associated with gastric cancer[2]. It is a common infection throughout the world, with prevalence ranging from below 20% in developed countries to over 80% in developing countries. Some risk factors for *H pylori* infection have been identified, such as low socio-economic status or poor hygiene[3]. However, there is remarkable inter-individual variability in susceptibility to the infection that cannot be explained by differences in environmental factors.

Another factor that may be related to *H pylori* infection susceptibility is the composition of the mucus gel layer in the stomach, in which *H pylori* resides. This layer protects the underlying epithelium from acid, proteases, mechanical trauma, and pathogenic micro-organisms and its main constituents are high molecular weight glycoproteins named mucins. These mucins consist of a polypeptide backbone with O-linked oligosaccharide side chains, to which the oligosaccharide side sequences are located in the central part of the mucins and consequently the susceptibility to *H pylori* infection[2,4].

Interestingly, there is substantial inter-individual variation in the number of these side chains. This is caused by a variable number tandem repeat (VNTR) polymorphism in the genes encoding for the mucins. VNTRs consist of repeated DNA sequences and the number of repeats is highly variable. The resulting repeated amino acid sequences are located in the central part of the mucin polypeptide backbone, to which the oligosaccharide side chains are attached[5]. Therefore, this polymorphism leads to the production of mucin polypeptides that substantially differ in both length and glycosylation[6,7]. Thus, this VNTR polymorphism may affect the protective properties of the mucins and consequently the susceptibility to *H pylori* infection.

Normal gastric mucosa is characterized by the expression of mucins MUC1, MUC5AC and MUC6. MUC1 is of the membrane-bound type, whereas MUC5AC and MUC6 are of the secreted, gel-forming type[8]. MUC6 and MUC1 show extensive VNTR variation,
MUC5AC only moderate\(^{[8,9]}\). Furthermore, the length of the repeated sequence differs: a single MUC6 tandem repeat sequence consists of 507 base pairs whereas single MUC1 and MUC5AC tandem repeat sequences consist of only 60 and 24 base pairs, respectively.\(^{[9]}\) Therefore, the VNTR polymorphism has the most profound impact on allele length and protein structure of MUC6.

Despite the significant structural consequences of these VNTR polymorphisms, few studies investigated their pathophysiological consequences. In a study comparing gastric cancer patients with healthy blood donors, shorter VNTR sections were associated with gastric cancer for MUC6\(^{[10]}\) and MUC1\(^{[11]}\). This effect may be mediated by an altered susceptibility to \(H\) pylori infection which is an important factor in gastric carcinogenesis, since Vinall et al.\(^{[8]}\) showed that short VNTR sections were associated with \(H\) pylori infection for MUC1. However, there are no data available regarding the relationship between \(H\) pylori infection and VNTR polymorphism in MUC6, which is abundant in the stomach and has the most extensive VNTR variation\(^{[2,3]}\).

Therefore, the aim of this study was to investigate the hypothesis that susceptibility to \(H\) pylori infection is related to MUC6 VNTR length. We studied a sample of 160 patients referred for upper gastrointestinal endoscopy and found that patients with short MUC6 allele fragments have a significantly higher risk of being infected with \(H\) pylori, which suggests that mucin 6 protein length modifies susceptibility to \(H\) pylori.

**MATERIALS AND METHODS**

**Subjects**

From September to December 2003, all patients with upper gastrointestinal symptoms visiting the Gastroenterology Outpatient Clinic of the Can Tho General Hospital for upper gastrointestinal endoscopy were asked to participate in this study. Patients who had not been treated for \(H\) pylori infection in the past and who gave written informed consent were included in the study. At baseline, data regarding age, gender, smoking habits and alcohol consumption were registered.

**Diagnosis of \(H\) pylori infection**

All patients had a \(^{13}\)C urea breath test (Heliprobe\(^{TM}\), Noster system AB, Stockholm, Sweden). Patients were not allowed to use proton pump inhibitors/H\(_2\)-receptor antagonists or antibiotics during the two weeks preceding the breath testing. After an overnight fast patients took a Helicap\(^{TM}\) capsule (containing 1 \(\mu\)g of \(^{13}\)C urea) with 50 mL of water. Ten minutes later, a breath sample was collected (BreathCard\(^{TM}\) and analyzed during 4 min. Measuring more than 50 counts was regarded as proof of \(H\) pylori infection, measuring fewer than 25 counts was regarded as proof of absence of \(H\) pylori infection\(^{[13]}\).

**Determination of MUC6 allele length**

Blood samples were collected for DNA isolation (Puregene\(^{TM}\) kit, Gentra systems, Minneapolis, USA). MUC6 allele fragment length was measured using Southern blot analysis. The DNA samples were digested with the \(Pvu\) II restriction enzyme as described previously by Vinall et al.\(^{[8]}\). This enzyme cuts just outside the tandem repeat domain and clearly reveals the MUC6 VNTR polymorphism. The resulting DNA fragments were separated by agarose gel electrophoresis (0.7% agarose in 0.04 mol/L Tris, 0.001 mol/L EDTA, pH 8.0) at 35 V for 18 h. We used \(\lambda\)-Hind III digest as a marker of DNA fragment length. DNA fragments were then transferred onto nylon membranes (Gene Screen Plus\(^{TM}\) hybridization transfer membrane, Boston, USA). Afterwards, the nylon membranes were treated with ultraviolet radiation and prepared for hybridization by Church buffer. The probe, which consisted of two MUC6 tandem repeats, was produced by polymerase chain reaction with forward primer 5’-ACCTCTTTGGTT-GACTCCAATTA-3’ and reverse primer 5’-AACGT-GAGTGGGAAGTGTGGT-3’ and randomly labelled with \(^{32}\)PdCTP. The resulting PCR product was verified by sequencing. After 18 h of hybridization of the probe in 0.5 mol/L phosphate buffer containing 7% SDS and 0.001 mol/L EDTA, SSPE/SDS-solutions were used to remove non-specifically bound probe. Using the \(\lambda\)-HindIII digest as a reference, the individual MUC6 allele fragment lengths were calculated.

**Statistical analysis**

The primary outcome of this study was the presence or absence of \(H\) pylori infection. For analysis, MUC6 allele fragment length was dichotomized as being either short (\(\leq 13.5\) kb) or long (>13.5 kb) and patients were classified according to genotype [long-long (LL), long-short (LS), short-short (SS)]. Baseline characteristics for \(H\) pylori positive and negative patients were compared. MUC6 genotype and baseline characteristics were related to \(H\) pylori infection by means of unadjusted and adjusted logistic regression analyses, using the SAS\(^{®}\) statistical software package (SAS Institute Inc., USA). Statistical significance was defined as a \(P < 0.05\). Missing values were excluded from analysis.

**RESULTS**

**Population**

During the study period, 160 patients [mean age 43 years, 58 (36%) males, 92 (58%) \(H\) pylori infected] were included. Table 1 shows that \(H\) pylori positive and negative patients were comparable for all baseline characteristics except age.

**MUC6 allele fragment length**

Using the restriction enzyme \(Pvu\) II, a clear length polymorphism was detected. Minimum fragment length difference was 0.5 kb, reflecting the length of a single MUC6 tandem repeat that consists of 507 base pairs. MUC6 was found to be highly polymorphic with \(Pvu\) II-restricted fragment lengths ranging from 7 to 19 kb [mean 13.8 kb (SD: 2)] (Figure 1).

**Factors associated with \(H\) pylori infection (Table 2)**

Mean MUC6 allele fragment length was shorter for \(H\) pylori positive patients than for \(H\) pylori negative patients (13.4
Since there were too many different allele fragment lengths to analyse separately, MUC6 allele fragment length was dichotomized as being either short (≤ 13.5 kb) or long (> 13.5 kb). Furthermore, patients were grouped according to genotype [long-long (LL), long-short (LS), short-short (SS)]. Patients with two short allele fragments were more often infected with *H pylori* than patients with one long and one short allele fragment [Odds ratio (95% CI): 2.41 (1.0-5.7)] or patients with two long allele fragments [4.24 (1.8-10.0)]. Figure 2 shows that there seems to be a gradual increase in prevalence of *H pylori* infection from 43% (24/56) for patients with two long allele fragments, through 57% (25/58) for patients with one long and one short allele fragments, to 76% (11/14) for patients with two short allele fragments.

Additionally, Table 2 shows that of the other patient characteristics measured, only age was associated with *H pylori* infection, and that the influence of MUC6 genotype remained virtually unchanged after adjusting for age group, gender, smoking and alcohol consumption.

**DISCUSSION**

The aim of this study was to investigate the relationship between MUC6 VNTR polymorphisms and *H pylori* infection. We were able to confirm that MUC6 VNTR length is highly polymorphic and our data suggest that *H pylori* infection is more frequent in patients with short MUC6 alleles.

Few other studies investigated the MUC6 VNTR polymorphism. Vinall *et al* [6] found 11 different allele fragment lengths for MUC6, ranging from 8 to 13.5 kb. This degree of variation is considerably lower than in our study. It is unlikely that this difference in VNTR length variation is inherent to the Southern blotting technique, as we used the same restriction enzyme. However, the aforementioned study used the Centre d’Étude du Polymorphisme Humain (CEPH) series of families in France and these may be much more homogeneous than our study population.

The relationship between *H pylori* infection and mucin VNTR length has been investigated for another mucin gene, MUC1, and the results were similar to ours. Like other mucins, MUC1 lubricates epithelial structures and constitutes a barrier against acid, proteases and pathogenic organisms. Vinall *et al* [9] showed that short MUC1 alleles were associated with *H pylori*-induced gastritis. Therefore, MUC1 and MUC6, although arising from different families of mucins, may be involved in the same mechanism regarding *H pylori* infection [14].

Our results are also compatible with research focusing

*Nguyen TV et al. MUC6 and *H pylori* [6023](www.wjgnet.com)*
on the relationship between mucin allele length and gastric cancer. In a study investigating 157 gastric cancer patients, it was found that short MUC6 alleles were more frequent in patients with gastric cancer than in healthy donors.\textsuperscript{[9]} This seems to be in line with our results that short MUC6 alleles are associated with \textit{H. pylori} infection. In fact, because \textit{H. pylori} has been classified as a class I carcinogen, the higher prevalence of \textit{H. pylori} infection among patients with short MUC6 alleles may (partly) explain the higher prevalence of gastric cancer in these patients. Again, the same goes for MUC1 since Carvalho \textit{et al}\textsuperscript{[11]} stated that short MUC1 alleles were associated with gastric cancer. More research is necessary to determine whether these relationships are independent.

However, other researchers claimed that MUC5AC, and not MUC6, is important in \textit{H. pylori} infection: Van den Brink \textit{et al}\textsuperscript{[8]} stated that \textit{H. pylori} co-localised with MUC5AC but not with MUC6, and Van de Bovenkamp \textit{et al}\textsuperscript{[9]} stated that MUC5AC, and not MUC6, was the most important receptor for \textit{H. pylori}. However, in the study by Van den Brink \textit{et al}, antibodies recognizing the MUC6 precursor rather than mature MUC6 were used. Therefore, it seems plausible that the precursor MUC6 is only found in neck and gland cells, where MUC6 is synthesized. However, the mature MUC6, which is secreted, may be found throughout a much larger area. In fact, Ho \textit{et al}\textsuperscript{[17]} recently confirmed that the mucin within the glands consisted entirely of MUC6, but they also showed that, although the mucus layer on the gastric surface consisted primarily of MUC5AC, layers of MUC6 were interspersed between the layers of MUC5AC.

Regarding the receptor function of the mucins, MUC5AC is the primary source of Lewis B (Le\textsuperscript{b}), a terminal carbohydrate chain that acts as a ligand for the bacterial adhesion molecule BabA\textsuperscript{[16,18]}. However, although other receptor sites may be present on MUGC\textsuperscript{[19]}, mucins may be involved in many other processes besides bacterial binding.

In fact, recently, Kawakubo \textit{et al}\textsuperscript{[20]} showed that secretions from the glands (consisting of MUC6) may have an antibiotic effect on \textit{H. pylori}, while secretions from the superficial epithelium (primarily consisting of MUC5AC) may have a pro-biotic effect, thereby limiting \textit{H. pylori} infection to the superficial epithelium and protecting the deeper layers of the gastric mucosa. This is consistent with the geographical distribution of \textit{H. pylori} described by Van den Brink \textit{et al}\textsuperscript{[3]}. The antibiotic effect was mediated by terminal \( \alpha-1,4 \)-linked N-acetylgalcosamine (\( \alpha-1,4 \)-GlcNAc) residues, which are present on the variable region of MUC6. Furthermore, the presentation of multiple terminal \( \alpha-1,4 \)-GlcNAc residues as a cluster may be important for achieving optimal activity. This may explain our finding that shorter MUC6 molecules, which have fewer \( \alpha-1,4 \)-GlcNAc residues and therefore lower antimicrobial activity, are associated with \textit{H. pylori} infection. More research is necessary to further elucidate the functions of the mucins.

**ACKNOWLEDGMENTS**

The authors would like to thank Saskia Bergevoet for performing the Southern Blots and the American Gastro-enterology Association for the opportunity to present this paper at the Digestive Disease Week (May 2005, Chicago).
