ABSTRACT

Annexin A5 (anxA5) is abundantly present in seminal plasma, however, its endogenous function in seminal plasma is not known. Recently, we demonstrated that folic acid and zinc sulfate intervention increased sperm count. To explore the involvement of anxA5 in human (sub)fertility, we measured anxA5 concentrations in seminal plasma, using sandwich ELISA, before and after folic acid (5 mg/day) and zinc sulfate (66 mg/day) intervention in 86 fertile and 78 subfertile males participating in a randomized placebo controlled intervention study. Seminal plasma anxA5 concentrations at baseline were not significantly different between fertile and subfertile males, (median) 5.2 µg/ml (25th–75th percentile: 4.2–7.2), and 5.6 µg/ml (4.3–6.7), respectively. The various treatments did not affect seminal plasma anxA5 concentrations. In conclusion, seminal plasma anxA5 concentration is not associated with male factor subfertility and the observed increase in sperm count after folic acid and zinc sulfate treatment cannot be explained by a change in the seminal plasma anxA5 concentration. Further studies are needed to elucidate the mechanisms responsible for the beneficial effect of this intervention treatment on sperm count.

INTRODUCTION

Subfertility is a common disorder with a prevalence of about 15% in all couples in the Western world.1,2 In about half the number of cases a male factor is identified, defined as male factor subfertility. In most cases, subfertility is regarded as idiopathic, however, gene-environment interactions are suggested to be involved.3 The environmental causes are particularly of interest, because they are better amenable to curative and/or preventive measures than genetic factors. A significant but largely neglected environmental factor is nutrition. It is well known that nutrition plays an important role in reproduction.4 The vitamin folate is known to contribute to the prevention of neural tube defects when taken periconceptionally.5,6 Folate plays an important role in the synthesis of transport ribonucleic tRNA. It has been shown that zinc is essential in testicular development.8 Also, seminal plasma zinc concentrations influence the oxygen consumption of spermatozoa,9,10 nuclear chromatin condensation,11 acrosome reaction,12 and acrosin activity.13 Furthermore, the synthesis of testosterone in the Leydig cells and the conversion of testosterone to 5α-dihydrotestosterone by the 5α-reductase enzyme is dependent on zinc supply.14

Recently, we conducted an intervention study supplying both folic acid and zinc sulfate to fertile and subfertile men, and found that after 26 weeks of intervention treatment, subfertile men had a 74% increase in normal sperm count.15 Despite the knowledge that zinc and folate are essential for the synthesis of genetic material, the precise underlying mechanism by which these micronutrients affect spermatogenesis is not clear.

AnxA5 is a member of the protein family of annexins, which contains more than ten members. These proteins (especially anxA5) are characterized by their high affinity for negatively charged phospholipids present in cell membranes.16 AnxA5 is primarily known because of its world-wide use to detect apoptosis in vitro and also experimentally in vivo.17,18 Due to the affinity to negatively charged phospholipids, anxA5 is a potent inhibitor of blood coagulation and inflammation.19 It is also known that anxA5 is abundantly present in seminal plasma.20

Because our research group has not yet identified the underlying mechanism of the beneficial effect of folic acid and zinc sulfate on spermatogenesis, and because of the...
with a Makler counting chamber. An aliquot of semen was centrifuged at 1,400 x g (Hettich 16A, 1323 rotor) for 10 minutes. The supernatant seminal plasma was frozen without preservative.

In the referred study, fertile males were recruited from nine midwifery practices in the surrounding areas of Nijmegen, in The Netherlands. These healthy men, without a history of fertility problems at the moment of enrollment, had a pregnant partner who conceived spontaneously within one year of regular, unprotected intercourse. Subfertile males were recruited from the fertility clinics of the University Medical Centre Nijmegen and the Canisius Wilhelmina Hospital in Nijmegen. Subfertility was defined as failure of the female partner to conceive after one year of regular, unprotected intercourse and a sperm concentration between five and twenty million spermatozoa per mL on the first routine semen analysis after referral to the fertility clinic. The females of these subfertile males were not further evaluated, because the main focus was on the effect of folic acid and zinc sulfate treatment on seminal parameters in subfertile males. The fertile and subfertile males were included after having given their written informed consent and assigned to the four intervention groups by computer-generated random numbers. The interventions consisted of a daily dose of folic acid (5 mg) and placebo, zinc sulfate (66 mg) and placebo, or a combined dose of folic acid and zinc sulfate, or placebo/placebo throughout 26 weeks.

Before and after intervention one standardized semen sample was obtained from every participant for semen analysis according to World Health Organization (WHO) guidelines. The semen samples were produced by the participants via masturbation after an abstinence period of at least three to five days. These samples were delivered within one hour after production to the fertility laboratory. In this hour the participants were advised to keep the sample at room temperature. After liquefaction, an aliquot of semen was centrifuged at 1,400 x g (Hettich 16A, 1323 rotor) for 10 minutes. The supernatant seminal plasma was frozen without preservative and stored at -80˚C until assayed. Sperm concentration was determined by comparison between the baseline and post-intervention seminal plasma anxA5 concentration by the Wilcoxon Signed Ranks test. We corrected for a possible placebo-effect by comparing the delta anxA5 concentration for males receiving placebo with the delta anxA5 concentration for males receiving treatment.

Materials and Methods

From the randomized, placebo controlled trial designed to study the effect of folic acid and zinc sulfate on seminal parameters, samples were taken before and after intervention from 86 fertile and 78 subfertile males were available for the determination of endogenous anxA5 concentrations.

In the referred study, fertile males were recruited from nine midwifery practices in the surrounding areas of Nijmegen, in The Netherlands. These healthy men, without a history of fertility problems at the moment of enrollment, had a pregnant partner who conceived spontaneously within one year of regular, unprotected intercourse.

Subfertile males were recruited from the fertility clinics of the University Medical Centre Nijmegen and the Canisius Wilhelmina Hospital in Nijmegen. Subfertility was defined as failure of the female partner to conceive after one year of regular, unprotected intercourse and a sperm concentration between five and twenty million spermatozoa per mL on the first routine semen analysis after referral to the fertility clinic. The females of these subfertile males were not further evaluated, because the main focus was on the effect of folic acid and zinc sulfate treatment on seminal parameters in subfertile males.

The fertile and subfertile males were included after having given their written informed consent and assigned to the four intervention groups by computer-generated random numbers. The interventions consisted of a daily dose of folic acid (5 mg) and placebo, zinc sulfate (66 mg) and placebo, or a combined dose of folic acid and zinc sulfate, or placebo/placebo throughout 26 weeks.

Before and after intervention one standardized semen sample was obtained from every participant for semen analysis according to World Health Organization (WHO) guidelines. for males receiving the folic acid, zinc sulfate, or combined intervention treatment. The p values were two tailed and p ≤ 0.05 was considered statistically significant. Statistical analysis was performed using SPSS 10.0 for Windows software (SPSS Inc, Chicago, IL, USA).

RESULTS

AnxA5 concentration in seminal plasma. Although anxA5 could be determined in seminal plasma, it did not show an association with male fertility. The median (25th–75th percentile) baseline seminal plasma anxA5 concentrations was 5.2 µg/mL (4.2–7.2) in fertile (Table 1A) and 5.6 µg/mL (4.3–6.7) in subfertile males (p = 0.96, Table 1B).

Effect of intervention on seminal plasma AnxA5 concentration. Tables 1A and 1B show the effects of all interventions on seminal plasma anxA5 concentration in both fertile and subfertile males, respectively. We observed no effect of the combination treatment with folic acid and zinc sulfate on anxA5 concentration in both fertile and subfertile males (from 4.9 µg/mL (3.6–7.1) to 3.4 µg/mL (1.8–6.6) in fertile males and from 5.6 µg/mL (2.5–6.1) to 3.7 µg/mL (2.1–5.7) in subfertile males). All the other intervention types (placebo, folic acid, and zinc sulfate intervention) also did not significantly affect the anxA5 concentrations, neither in fertile, nor in subfertile males.

AnxA5 site of synthesis. To get some global insight in the synthesis of anxA5, the anxA5 mRNA concentrations and immunohistochemical localization of anxA5 protein were determined. AnxA5 mRNA concentrations appeared to be approximately twice as high in the prostate (ΔCt 5.0) as compared to the testis (ΔCt 3.8). Furthermore, as shown in Figure 1, immunohistochemical staining of anxA5 revealed strong staining in the prostate and some staining in the testis. In the prostate mainly the glandular epithelium is stained. In the testis a gradual staining of anxA5 was observed. The highest intensity is nearby the spermatoocytes. The spermatogonia are not stained.

DISCUSSION

This study was performed to explore if anxA5 is associated with male factor subfertility and to find an underlying mechanism for the intriguing observation that folic acid and zinc sulfate intervention increases the sperm count in subfertile males.15,21 Remarkable was the finding that the endogenous seminal plasma anxA5 concentrations were at least 1000-fold higher compared to the concentrations of anxA5 in blood plasma of healthy volunteers, in which anxA5 concentrations up to 5 ng/mL are found.23,25

The baseline seminal plasma anxA5 concentration, however, was not significantly different between fertile and subfertile males. This strongly suggests that it is not very likely that anxA5 is associated with sperm concentration. Therefore, anxA5 is probably not involved in male factor subfertility.

Our data suggest that anxA5 is not produced by the spermatozoa themselves, since the immunohistochemical results indicate that the spermatoocytes themselves are not stained. Furthermore, the real time mRNA analysis shows that the prostate is the most important organ in the production of anxA5 in seminal plasma.

Only one other study could be found in which the authors investigated the concentration of anxA5 in seminal plasma. These authors obtained semen samples from normal or vasectomized patients and found anxA5 concentrations of approximately 20 µg/mL.20 It is remarkable that these authors found an almost 4 times higher anxA5 concentration in seminal plasma compared to our findings. A possible explanation for this difference in anxA5 concentration is the method used to measure these concentrations. Christmas et al.20 pooled all their seminal plasma, purified the annexins present in the seminal plasma using an affinity column coated with phospholipids to which the annexins bind, and thereafter used SDS-PAGE and immunoblot analysis to determine if anxA5 was present in seminal plasma. The concentrations of anxA5 in seminal plasma were estimated by comparing the immunostaining intensity of immunoreactive bands with known standards of placental anxA5. In comparison to our ELISA procedure the method used by Christmas et al.20 is only semi-quantitative which may explain the higher yields of anxA5 from seminal plasma. Christmas et al.20 further state that the annexins in seminal plasma are actively secr eted by the prostate, it being the main producer of seminal plasma anxA5, which is in agreement with our findings. They exclude the epididymis as a possible source of annexin because the seminal plasma annexin concentrations are not changed by vasectomy. This is consistent with our finding that the anxA5 concentrations were not significantly different between fertile and subfertile males at baseline.

The question remains what the possible link can be between increases in sperm count in subfertile males after folic acid and zinc sulfate intervention and the seminal plasma anxA5 concentration. An interesting hypothesis is the effect of both nutrients on the control of apoptosis. Spontaneous death of certain classes of germ cells has been shown to be a constant feature of normal spermatogenesis in a variety of mammalian species, including man.26,27 Scarce information is available on the biological significance of apoptosis in spermatogenesis or its possible role in male fertility.28 Since it is known that endogenous anxA5 binds to apoptotic cells in vivo, possibly the seminal plasma anxA5 concentration reflects the grade of apoptosis of spermatozoa and other cell types involved in spermatogenesis and seminal fluid production.
Another possible link between seminal plasma anxA5 concentration and sperm concentration is related to the function of anxA5 as an inhibitor of inflammation. It is well known that subfertile men have higher leukocyte numbers in their semen compared to their fertile counterparts, the frequency of leukocytospermia (>10^6 white blood cells/mL semen) being between 10–20% among infertile males. Sperm damage by white blood cells can amongst others be mediated by proteases and cytokines, released during inflammation reactions. Since anxA5 inhibits inflammation it could have a protective effect in these situations, keeping sperm counts up.

In conclusion, the results presented in the present paper do not support that anxA5 is associated with male factor subfertility. Intervention with folic acid and zinc sulfate does not affect seminal plasma anxA5 concentration. Therefore, it is not very likely that the observed increase in sperm count after intervention can be attributed to a possible decrease in apoptosis rate of cells involved in spermatogenesis or protection to inflammation by endogenous seminal plasma anxA5 concentration. Further research is needed to clarify the underlying mechanisms responsible for the observed increase in sperm count after folic acid and zinc sulfate intervention.
