Abstract

Inclusive jet production, $e^+e^- \rightarrow e^+e^-\text{ jet }X$, is studied using 560 pb$^{-1}$ of data collected at LEP with the L3 detector at centre-of-mass energies between 189 and 209 GeV. The inclusive differential cross section is measured using a $k_t$ jet algorithm as a function of the jet transverse momentum, $p_t$, in the range $3 < p_t < 50$ GeV for a pseudorapidity, $\eta$, in the range $-1 < \eta < 1$. This cross section is well represented by a power law. For high $p_t$, the measured cross section is significantly higher than the NLO QCD predictions, as already observed for inclusive $\pi^\pm$ and $\pi^0$ production.
1 Introduction

Two-photon collisions are the main source of hadron production in the high-energy regime of LEP via the process $e^+e^- \rightarrow e^+e^-\gamma^*\gamma^* \rightarrow e^+e^-\text{hadrons}$. Hadrons with high transverse momentum are produced by the direct QED process $\gamma^*\gamma^* \rightarrow q\bar{q}$ or by QCD processes originating from the partonic content of the photon. Next-to-leading order (NLO) QCD calculations are available [1, 2] for inclusive jet production in quasi-real two-photon interactions.

The L3 Collaboration published results on inclusive $\pi^0$, $K_S^0$ [3] and charged hadron [4] production in quasi-real two-photon collisions. The inclusive $\pi^0$ and $\pi^\pm$ differential cross sections, measured as a function of transverse momentum, exhibit a clear excess over NLO QCD calculations [5] for large transverse momentum. In this Letter, inclusive jet production is studied, in similar two-photon interactions, for a centre-of-mass energy of the two interacting photons, $W_{\gamma\gamma}$, greater than 5 GeV. The jets are measured in the transverse momentum range $3 < p_t < 50$ GeV and in the pseudo-rapidity interval $|\eta| < 1$. The analysis of jet production allows a comparison of the measurements to NLO QCD predictions, expected to be largely independent of fragmentation functions and hadronisation models.

2 Data and Monte Carlo

The data used for this analysis were collected by the L3 detector [6] at centre-of-mass energies $\sqrt{s} = 189 - 209$ GeV, with a luminosity weighted average value of $\sqrt{s} = 198$ GeV, and a total integrated luminosity of 560 pb$^{-1}$. Results on inclusive jet production at LEP for a smaller data sample at lower $\sqrt{s}$ were previously reported [7].

The process $e^+e^- \rightarrow e^+e^-\text{hadrons}$ is modelled with the PYTHIA [8] event generator with an event sample two times larger than the data. In this generator, each photon can interact as a point-like particle (direct process), as a vector meson (VDM process) or as a resolved photon (resolved process), leading to six classes of events. Since both incoming photons are assumed to be on the mass shell, PYTHIA is modified to generate the photon flux in the Equivalent Photon Approximation [9]. Predictions from the PHOJET [10] Monte Carlo program are also compared with the data. The following Monte Carlo generators are used to simulate the relevant background processes: KK2f [11] for $e^+e^- \rightarrow q\bar{q}$ ($\gamma$); KORALZ [12] for $e^+e^- \rightarrow \tau^+\tau^-$ ($\gamma$); KORALW [13] for $e^+e^- \rightarrow W^+W^-$ and DIAG36 [14] for $e^+e^- \rightarrow e^+e^-\tau^+\tau^-$. Jet hadronisation is simulated with the JETSET [8] parton shower algorithm. Events are simulated in the L3 detector using the GEANT [15] and GHEISHA [16] programs and passed through the same reconstruction program as the data. Time dependent detector inefficiencies, as monitored during each data taking period, are included in the simulations.

3 Event selection

Two-photon interaction events are collected predominantly by the track triggers [17] with a low transverse momentum threshold of about 150 MeV. The selection of $e^+e^- \rightarrow e^+e^-\text{hadrons}$ events [18] consists of:

- A multiplicity cut. To select hadronic final states, at least six objects must be detected, where an object can be a track satisfying minimal quality requirements or a calorimetric cluster of energy greater than 100 MeV.
• Energy cuts. To suppress background from beam-gas and beam-wall interactions, the total energy in the electromagnetic calorimeter is required to be greater than 500 MeV. In order to exclude $e^+e^-$ annihilation events, the total energy deposited in the calorimeters must be less than $0.4 \sqrt{s}$.

• An anti-tag condition. Events with a cluster in the luminosity monitor, which covers the angular region $31 < \theta < 62$ mrad, with an electromagnetic shower shape and energy greater than 30 GeV are excluded.

• A mass cut. The mass of all the visible particles of the event, including clusters in the luminosity monitor, must be greater than 5 GeV. In this calculation, the pion mass is attributed to tracks and electromagnetic clusters are treated as massless. The visible mass distribution for data and Monte Carlo is shown, after all cuts, in Figure 1. A wide range of masses is accessible.

About 3 million hadronic events are selected by these criteria. The background level of this sample is less than 1% and is mainly due to the $e^+e^- \rightarrow q\bar{q}(\gamma)$, $e^+e^- \rightarrow \tau^+\tau^-$ and $e^+e^- \rightarrow e^+e^-\tau^+\tau^-$ processes.

4 Jet definition and composition

Jets are formed from good quality tracks and electromagnetic clusters. The tracks have a transverse momentum greater than 400 MeV, an absolute pseudorapidity less than 1 and a distance of closest approach to the primary vertex in the transverse plane less than 4 mm. The number of hits must be greater than 80% of the maximum number expected from the track angle. For a transverse momentum less than 20 GeV, the momentum and direction of the tracks are measured with the central tracker. For the tracks with transverse momentum above 20 GeV, the track momenta are replaced with that derived from the energy of their associated cluster in the electromagnetic and hadronic calorimeters, assuming the pion mass. Tracks associated with muon chamber hits are rejected. An electromagnetic cluster must have an energy greater than 100 MeV in at least 2 neighbouring BGO crystals and an absolute pseudorapidity less than 3.4. There should be no charged track within an angle of 200 mrad around the cluster direction and the associated energy in the hadron calorimeter must be less than 20% of the electromagnetic energy.

Jets are constructed using the $k_t$ jet algorithm KTCLUS [19]. This algorithm uses cylindrical geometry in which the distance between two objects $i$, $j$ of transverse momenta $p_{ti}$ and $p_{tj}$ is defined as $d_{ij} = \min(p_{t_i}^2, p_{t_j}^2)(\eta_i - \eta_j)^2 + (\Phi_i - \Phi_j)^2)/D^2$ where $\eta_i$ and $\eta_j$ are the pseudorapidities of the objects, $\Phi_i$ and $\Phi_j$ their azimuthal angles with respect to the beam axis and $D$ is a parameter of the algorithm which determines the size of the jet. The standard value $D = 1$ is used. A distance parameter $d_k$ equal to $p_{t_k}^2$ is also associated to each object. At the first iteration of the algorithm, the objects are the tracks and electromagnetic clusters defined above. At each iteration of the algorithm, the $d_{ij}$ and $d_k$ are ordered. If the smallest distance is a $d_{ij}$, the corresponding objects $i$ and $j$ are replaced by a new object, a “precluster”, formed by adding the 4-momenta of the objects $i$ and $j$. If the smallest distance is a $d_k$ associated with a particle, this is considered as a “beam jet” particle and is removed from the list of objects. If the smallest distance is a $d_k$ associated with a precluster, this defines a “hard jet” and is removed from the list of objects. The procedure is iterated until all objects define beam or hard jets. Only hard jets with $p_t > 3$ GeV and $|\eta| < 1$ are further considered for this analysis.
In Table 1, the data are compared to the Monte Carlo at reconstructed and generated levels for: the number of jets, the mean number of jets per event with at least one jet, the mean number of particles per jet and outside the jets. For different $p_t$ intervals, comparisons are made of the mean number of tracks and electromagnetic clusters per jet and of transverse momentum of the leading particle divided by that of the jet. The standard deviations of these distributions are also quoted. For Monte Carlo at generator level, all particles with mean life time less than $3 \times 10^{-10}$ s are allowed to decay and jets are formed from the photons, charged pions, charged and neutral kaons, protons and neutrons. Both Monte Carlo programs underestimate the number of particles inside and outside the jets. The predicted number of electromagnetic clusters is too low for all $p_t$. The amount of energy carried by the most energetic particle of the jet is correctly reproduced, except in the highest $p_t$ interval. The number of particles per jet is shown in Figure 2.

Figure 3 shows the distributions of $|\eta|$ for particles, i.e. clusters and tracks, tracks and jets in two intervals of the jet transverse momentum, $p_t < 20$ GeV and $p_t \geq 20$ GeV. The detector acceptance for tracks, calorimetric clusters and jets is well reproduced by Monte Carlo models.

5 Differential cross section

The differential cross section for inclusive jet production as a function of $p_t$ is measured for $W_{\gamma\gamma} \geq 5$ GeV, with a mean value of $\langle W_{\gamma\gamma} \rangle \simeq 30$ GeV, and a photon virtuality $Q^2 < 8$ GeV$^2$, with $\langle Q^2 \rangle \simeq 0.2$ GeV$^2$. This phase space is defined by Monte Carlo generator-level cuts. Results are presented in 9 $p_t$ bins between 3 and 50 GeV.

The $p_t$ distribution of the jets is presented in Figure 4. The total background is listed in Table 2. Events from the $e^+e^- \rightarrow e^+e^-\tau^+\tau^-$ process dominate the background at low $p_t$ while hadronic and tau-pair annihilation events dominate it at high $p_t$. To measure the cross section, the background is subtracted bin-by-bin. The migration due to the $p_t$ resolution is corrected by a one-step Bayesian unfolding [20]. The data are corrected for the selection efficiency which includes acceptance, and is calculated bin-by-bin as the ratio of the number of fully simulated jets selected in PYTHIA over the number of generated jets, as formed by the KTCLUS algorithm applied to particles at generator level. The efficiency decreases with $p_t$ from 61% to 15%.

The level 1 trigger efficiency is obtained by comparing the number of events accepted by the independent track and calorimetric energy triggers [21]. It varies from 97% to 100%. The efficiency of higher level triggers is about 98% and is measured using prescaled events. The differential cross section and the overall efficiency, which take into account selection and trigger efficiencies, are given as a function of $p_t$ in Table 2.

Sources of systematic uncertainties on the cross section measurements are the uncertainties on the estimation of the selection and trigger efficiencies, the limited Monte Carlo statistics, the background subtraction procedure, the selection procedure and the Monte Carlo modelling. Their contributions are shown in Table 3. The uncertainty due to the selection procedure is evaluated by repeating the analysis with different selection criteria: the multiplicity cut is moved to 5 and to 7 objects, the requirement on the number of hits of the tracks is moved to 70% of those expected, the isolation angle of clusters is moved to 100 mrad, and jets with a particle accounting for more than 90% of the jet transverse momentum are rejected. The sum in quadrature of the differences between these and the reference results is assigned as systematic uncertainty in Table 3. Varying other criteria, such as the energy cut, the minimum cluster energy or the threshold where the track energy is defined by calorimeters, gives negligible contributions. To
evaluate the uncertainty on the Monte Carlo modelling, the selection efficiency is determined
using only one of the PYTHIA subprocesses: VDM-VDM, direct-direct or resolved-resolved.
The systematic uncertainty is assigned as the maximum difference between these values and
the reference Monte Carlo.

The differential cross sections as a function of |η| are uniform within the experimental
uncertainties for both $p_t < 20$ GeV and $p_t > 20$ GeV, albeit in the latter case these uncertainties
are large.

The differential cross section $dσ/dp_t$ is described by a power law function $Ap_t^{-B}$, as expected
from the onset of hard QCD processes, with $B = 3.65 ± 0.07$. The result of the fit is shown in
Figure 5a together with a comparison to Monte Carlo predictions.

In Figure 5b the data are also compared to analytical NLO QCD predictions [2]. For
this calculation, the flux of quasi-real photons is obtained using the improved Weizsäcker-
Williams formula [22]. The interacting particles can be point-like photons or partons from the
$γ → qq$ process, which evolve into quarks and gluons. The GRV-HO parton density functions
of Reference 23 are used and all elementary $2 → 2$ and $2 → 3$ processes are considered. The
parameter $\Lambda^{(5)}$ is set to 130 MeV. The renormalization and factorisation scales are taken to be
equal: $μ = M = E_t/2$ [1]. To assign uncertainties, the scale is varied by a factor 1/2 or 2, which
gives a change in the prediction less than 20%. The results of this calculation agree [2] with
those described in Reference 24. An additional uncertainty in comparison with NLO QCD,
which is not considered here, might arise from the modeling of the hadronisation process. In
a similar study [25] it was evaluated to be below 10% for $p_t > 10$ GeV and decreasing with
increasing $p_t$. The agreement with the data is poor in the high-$p_t$ range, as previously observed
in the case of inclusive $\pi^0$ [3] and $π^±$ [4] production in similar two-photon reactions. In Figure
6, the data are divided in two $W_{γγ}$ ranges, $W_{γγ} > 50$ GeV and $W_{γγ} ≥ 50$ GeV and compared
to the analytical NLO QCD predictions [2]. For $W_{γγ} ≥ 50$ GeV there is a clear discontinuity
in the slope near $p_t = 25$ GeV, due to the direct contribution. At high $p_t$, the disagreement
between data and theoretical calculations is still present.
