We investigate the exciton energy level structure of a large ensemble of InAs/GaAs quantum rings by photoluminescence spectroscopy in magnetic fields up to 30 T for different excitation densities. The confinement of an electron and a hole in these type I quantum rings along with the Coulomb interaction suppress the excitonic Aharonov-Bohm effect. We show that the exciton energy levels are nonequidistant and split up in only two levels in magnetic field, reflecting the ringlike geometry. A model, based on realistic parameters of the self-assembled quantum rings, allows us to interpret the essential features of the observed PL spectra in terms of the calculated optical transition probabilities.

DOI: 10.1103/PhysRevB.80.155318

The excitonic energy structure of self-assembled quantum dots (QDs) is well studied.1,2 By magnetoluminescence experiments it has been demonstrated that the electronic energy levels in a QD can be described by the Fock-Darwin model for a two-dimensional harmonic oscillator in a magnetic field.3-5 Changing the QDs to ringlike structures modifies the energy spectrum, and gives rise to the Aharonov-Bohm (AB) effect: the oscillatory behavior of charge carriers in a ringlike geometry as a function of the magnetic flux threading the opening of the ring.6 If the magnetic field penetrates into the conducting region of the ring, the AB-type oscillations due to the magnetic flux threading the opening coexist with the diamagnetic shift of energy levels and are aperiodic (see, e.g., Refs. 11 and 12).

The optical emission of self-assembled InAs/GaAs quantum rings (QRs) (Refs. 13 and 14) has been studied experimentally without a magnetic field,15 and in magnetic fields not higher than 9 T.16 In general, excitons are neutral excitations, thus on forehand we do not expect any sensitivity to the magnetic flux. However, since the exciton is a polarizable composite particle, the area between the different trajectories of the electron and the hole determines the phase picked up by the exciton.17 Therefore the possible prominence of the AB effect for excitons strongly depends on their polarization. Calculations of the photoluminescence (PL) spectra of type I GaAs/AlGaAs and several type II QRs showed that a weak remniscence feature of the AB effect in the PL spectrum might be observed.18,19 Experimentally the optical AB effect has been shown in different ringlike structures.20-22 Recently, the exciton energy spectra for various models of the InAs/GaAs self-assembled QRs were calculated as a function of the applied magnetic field and it was shown that the spectra are very sensitive to the details of the QR shape.23

In this paper we consider the excitonic properties of self-assembled InAs/GaAs QRs in magnetic fields up to 30 T. Using different excitation densities we probe the magneto-PL of the ground and excited states. The essential features in the magneto-PL spectra are reproduced in calculations based on a realistic QR model.23-25 We will demonstrate that QRs have nonequidistant energy levels and exhibit a magnetic field induced splitting of the higher excitonic energy levels into two levels, in contrast to the n+1 fold degeneracy of the nth excited state of QDs with a harmonic confinement potential. Furthermore, we will show that the confinement of an electron and a hole along with the Coulomb interaction suppress the excitonic AB effect in these QRs.

For the PL studies, a sample containing a single layer of QRs (Refs. 13 and 14) is mounted in a liquid-nitrogen-cooled charge-coupled device camera. Static magnetic fields up to 30 T were applied parallel to the growth direction and the PL is detected in the Faraday configuration.

The dependence of the QR emission energy on the excitation density is shown in Fig. 1(a). The ground-state emission energy of the QRs is centered around 1.308 eV, typical for these nanostructures.14 The ground-state emission has an inhomogeneous broadening with a full width at half maximum of 20 meV. With increasing excitation density two additional peaks can be resolved. These peaks have an energy of 39 and 63 meV above the ground-state energy. The wetting layer (WL) emission is centered around 1.438 eV (not shown), which is 67 meV above the highest observed confined-state energy of the QRs.

We determine the energy of the ground-state PL by fitting the spectra at low excitation densities by a Gaussian. The observed ground-state emission energy E(B) of an exciton in a QD for relatively small B is approximately given by

\[ E(B) = E_0 \pm \alpha_B B + \frac{\omega_0}{\omega_0^2 + (\omega_0 - \omega)^2} \]

Here \( E_0 \) is the emission energy at \( B = 0 \) T, \( \omega_0 \) is the exciton \( g \) factor, \( \mu_B \) is the Bohr magneton, and \( \alpha_B \) is the diamag-
FIG. 1. (Color online) (a) PL as a function of excitation density, for which the lowest (highest) excitation density is 102 W cm⁻² (10⁵ W cm⁻²). Two excited states can be distinguished for higher excitation density located 38 and 63 meV above the ground-state emission energy. The inset shows the diamagnetic shift \( E_{\text{dia}} \) of the ground state. The quadratic fit (red line) is used to determine the diamagnetic coefficient \( \alpha_d \). (b) Excited states as a function of \( B \) in \( \sigma^- \) polarization for an excitation density of 10⁵ W cm⁻². The dashed lines are guides to the eye in order to follow the evolution of the peak positions in \( B \). The arrow indicates the emission energy at which for QDs a third peak is present. As opposed to QDs we observe a minimum in PL intensity.

The magnetic coefficient. The second term is the Zeeman term which gives rise to a spin-induced splitting of the exciton PL in a magnetic field. We define \( g_{\text{ex}} = \frac{\mu_B}{\hbar} \), and find \( g_{\text{ex}} = -1.7 \), in correspondence with previously reported values obtained on individual QRs and comparable to values for QDs. In the inset of Fig. 1(a) the diamagnetic shift \( E_{\text{dia}} \) is shown, defined by \( E_{\text{dia}} = \frac{E_0 + E_0}{2} - E_0 \). The diamagnetic shift has a smooth dependence on the magnetic field. From the quadratic fit (solid line) we find \( \alpha_d = 10 \mu eV/T^2 \), in agreement with previous reported values for QRs (Ref. 16) and QDs.

To investigate the influence of the ringlike geometry on the excitonic behavior in the excited states of the QRs, we measured the magneto-PL of these structures for higher excitation intensities. Figure 1(b) shows the higher excitation data in \( \sigma^- \) polarization as function of \( B \) in intervals of 5 T. The dashed lines are a guide to the eye and follow the peak positions. We have carefully assigned the PL peak positions as function of \( B \) by comparing the PL spectra at different \( B \) (see Fig. 2). As implied by Fig. 1(b), both resolvable excited states split up in two separate peaks. Each of the PL peaks of the QRs Zeeman splits further with a smaller energy separation into two peaks of opposite circular polarization.

To interpret the higher lying energy states, we will focus only on the states in the model having a large spectral transition probability [cf. Fig. 3(b)], and compare them with the experimentally observed PL peaks. The first-excited state is
expected at 20 meV above the ground-state emission energy. However, in our experimental data we cannot resolve this peak due to the inhomogeneous broadening. The second-excited state in our model is at 58 meV above the ground-state emission energy, and corresponds to the second peak in our experiment, whereas the calculated energy level at 1.42 eV, 82 meV above the ground-state emission, corresponds to the third peak we observe. In order to better compare the calculated spectra to the experimental spectra we introduce a Gaussian broadening $\Gamma$, which simulates the inhomogeneous broadening of the ensemble. For $\Gamma=10$ meV, we find the best comparison of the calculated spectra with the experimental data. Figure 4 shows the calculated PL spectra for $B$ up to 30 T in steps of 5 T. The calculated and measured spectra [cf. Fig. 1(b)] show a qualitative resemblance, although the absolute values of the energy splittings are different. Importantly, the introduced broadening indeed shows that the first-excited state is not resolvable in the magneto-PL. We do note that based on our model we assign the measured PL peaks to different excitonic states in the QRs as compared to the identification based on PLE measurements on single QRs.29 However, within the theoretical model, which was successfully applied to explain the magnetization behavior of QRs on similar samples,12,28 we found that for all realistic ring parameters the PL of the first-excited state is concealed by the ground-state luminescence if an inhomogeneous broadening of about 20 meV is included.

The excitonic behavior characteristic for ringlike struc-

FIG. 3. Calculated optical transition probabilities for a realistic QR in the case of (a) a noninteracting electron-hole pair and (b) an interacting electron-hole pair. The gray scale is logarithmic where black (white) corresponds to the highest (lowest) transition probability. The arrows correspond to the first excitonic AB resonance in the ground state.

FIG. 4. Calculated broadened optical transition probabilities $P$ as a function of the emission energy $E$ for $B=0$ to 30 T in 5 T steps.
model, we are able to find a qualitative agreement between the measurements and the calculations and thereby we can explain the essential features in our measurements.

To conclude, we have analyzed the emission energy of a large ensemble of self-assembled InAs/GaAs QRs in high magnetic fields. Our model shows that the confinement of an electron and a hole along with the Coulomb interaction suppress the excitonic AB effect in these nanostructures. The ring character of our nanostructures results in nonequidistant magnetic fields. Our model shows that the confinement of an excited state into two states. This is in contrast to what has been observed in QD measurements. The optical transition probabilities are calculated within our model, based on the characterization of a realistic QR. Comparing these calculations with our experimental data we find a qualitative agreement, which allows us to identify the different PL peaks and helps to explain the excitonic behavior in magnetic field.
