Abstract—Multi-Processor Systems-on-Chip (MPSoC) designs are constructed by assembling pre-designed parameterized components. Communications are crucial to their overall functionality and performance. Formal verification methods have been intensively applied to processing elements, e.g., microprocessors. Very little work has been done with respect to communication modules. We present the formal specification of a packet switched NoC and its proven refinement. At the specification level, routing decisions are computed at once before packets get injected in the network. In the implementation, routing decisions are distributed over each individual node. We prove that the implementation behaves according to its specification for a 2D-mesh NoC. All models and proofs have been checked using the ACL2 theorem proving system. To the best of our knowledge, this work constitutes the first cross-layer verification of on-chip communication networks.

I. INTRODUCTION

Formal verification often consists in showing that for every execution of an implementation there exists an execution of its abstract specification with the same visible effects. This approach has been successfully applied to processing elements (e.g. microprocessors [7], [8]). Multi-Processor Systems-on-Chip designs offer increased performance by combining several processing and memory cores on a single die. The interconnect is becoming crucial to the overall functionality of an MPSoC [13]. When the number of interconnected units grows, bus performances decrease. Networks-on-Chips (NoCs) [2] is a solution that could meet future system performance.

Regarding buses, the recent work of Böhmann and Melham is the only effort trying to fill the gap between abstract specifications and low level implementations [3]. Previous efforts concentrate on proving properties on low-level implementations using model-checking [11] or combination of model-checking with theorem proving [1]. Gebremichael et al. [5] provide a parametric analysis of part of the AEthereal NoC [6]. All these works considers implementations only. Regarding specifications, Schmaltz et al. [12], [4] propose a generic network model, named GeNoC. We present models that are variations of the GeNoC model. Each model is at a different abstraction level. Our contribution is a formal relation between instances of these models.

Our goal is to provide a methodology to support the abstract specification of NoCs and the proof that implementations conform to it. In this paper, we present an initial effort towards this goal. We present the formal specification of a packet switched NoC. At the specification level, routing decisions are computed at once before packets get injected in the network. In the implementation, routing decisions are distributed over each individual node, i.e., hop-by-hop. Details of the implementation model are available [14]. The original contribution of this paper consists of the definition of the specification model and the proof that the implementation behaves according to its specification for a 2D-mesh network based on the HERMES NoC [10]. All models and proofs have been checked using the ACL2 theorem proving system [9] and are available on the web1. To the best of our knowledge, this paper presents the first cross-layer verification of a NoC.

II. A NOC EXAMPLE: HERMES

HERMES [10] is based on a 2D mesh architecture (Fig. 1). Each node is made of an IP core and a switch. Each switch has five bi-directional ports: East, West, North, South connecting to the neighbor switches, and Local to the IP core.

The routing policy is based on a deterministic, minimal algorithm: the XY routing algorithm. Each packet is routed on one dimension at a time. It travels first along the X axis until the first coordinate of the destination is reached, and then travels along the Y axis. This algorithm is recalled in Fig. 2.

Each port of the switch has an input buffer queue. A Round Robin priority policy is used to access the output ports. If the requested port is busy, packets are blocked and the request signal remains active. The transmission between two different nodes is ruled by an handshake protocol.

XYRouting(from, to) :
if from = to /* destination reached */
then take the Local port
else
  if Xfrom != Xto
    /* change X */
    if Xfrom < Xto
      then take port East
      else take port West
  else /* change Y */
    if Yfrom < Yto
      then take port South
      else take port North

III. VERIFICATION APPROACH

A. NoC Abstraction, Interpreter, and Property

Our method consists of a NoC model, two abstraction levels for that model, and a NoC interpreter for each level. Both interpreters are simulators for networks composed of identical nodes following a generic router model. They are proven equivalent (Section VII). The generic model has a few design-dependent functions which constitute the user-input. These functions are the Link Layer protocol (e.g., handshake), the routing logic (e.g., XY), and the scheduling policy (e.g., packet switching). Together with the router model, they are described below. The main difference between the interpreters lies in the routing decisions. The specification (Layer 2) supports source routing, where routes are computed before sending packets. The implementation supports distributed routing where each node computes the next step in a route.

B. Network Model

We assume a generic architecture composed of an arbitrary but finite number of nodes and a finite number of connections between any two nodes. Each node is uniquely identified by its position. A node includes a local memory and a router. A router is defined by a set of ports and four functions: input and output units, routing control, and flow control (see Fig. 4). All nodes are identical.

The main elements of a port are the data and control signals, and internal buffers (Fig. 4). Formally, a port is a tuple \((addr, stat, data, buff)\), where \(addr\) is a unique address, \(stat\) stores the values of the control signals and other state components, \(data\) denotes the values of the data signals, and \(buff\) represents the value of the buffers.

An address is a tuple \((coor, pid, dir)\), where \(coor\) is the unique identifier of the node the port belongs to, \(pid\) the name of the port (e.g., \(west\), \(south\)), and \(dir\) the direction, i.e., ‘i’ for an input port or ‘o’ for an output port. The topology is a list where each element is a pair of port addresses \((p_i, p_j)\), which means that port \(p_i\) is connected to port \(p_j\). A node is defined as the set of ports, where the address of each port \(p\) is the same. These ports define the state of the node. The set of all ports of a network defines the state of the network.

Functions \(\text{ProcessInputs}\) and \(\text{ProcessOutputs}\) define the low level protocols which use the control signals to transfer the content of the data signals to the internal buffers in case of an input port, or to transfer the content of the buffers to the data signals in case of an output port.

Function \(\text{RouteControl}\) applies the routing logic to one or more ports of a node. It returns a list of routed ports, i.e., ports together with routing information. The only design-dependent function is function \(\text{routing-logic}\) which implements the routing algorithm.

Function \(\text{FlowControl}\) implements the switching technique, e.g., packet, circuit, or wormhole. In case of conflict, this function also resolves priorities. This function extracts from the routed ports the packets that are ready to be transmitted. The only design-dependent function is function \(\text{switch-ports}\) which effectively schedules packets. Those scheduled packets are moved to the output ports computed by the routing control function.

All these functions form function \(\text{router}\) (Fig. 5), which updates a node state. Note that a node is equipped with a memory which is available to each port and each function. Argument \(\text{nstmem}\) represents that memory. To simplify the presentation, we assume that such a memory element is given as input argument of any function that accesses it. This argument is not explicitly mentioned any further.
returns the list of arrived packets, the list of delayed packets, and the state of the network at the end of the simulation.

```
GeNoC-L2(m, ntkst, arr, z, topo, simL) :
if simL = 0 return arr,m,ntkst
else
    let (dep, del) be depart-L2(ntkst, m, z)
    in
    let newntkst be step-ntk-L2(dep, topo)
    in
    GeNoC-L2(del, newntkst, add(z,arr),
              z + 1,topo, simL-1)
```

Fig. 7. Function GeNoC-L2

Function depart-L2 controls packet injection. According to a user-defined criterion, it determines which packets can be in the network. At the specification level, this function uses source routing and appends to a packet its route from its source to its destination. It inserts this extended packet in the local input port of its source node. It returns a new state (dep) and a list of delayed packets (del). Function step-ntk-L2 (see below) actually performs one simulation step. It updates the global network state. Those packets that are at their destination are extracted from this new state and appended to accumulator arrived. The next recursive call processes the delayed packets, the new network state, and time is incremented by 1.

```
step-ntk1-L2(ntslist, ntkst):
if ntslist = null return ntkst
else
    let newnstlist be ProcessInputs-L2(ntslist) in
    let (newnstlist,newntkmem1) be
        RouteControl-L2(newnstlist,ntkmem) in
    in
        step-ntk-L2(ports-nodelist(ntkst), ntkst)
    in
        return ProcessOutputs-L2(newnstlist),
               newntkmem

step-ntk-L2(ntkst, topo):
    let newntkst be
        step-ntk1-L2(ports-nodelist(ntkst), ntkst)
    in
        updateNeighbours-L2(newntkst,topo)
```

Fig. 8. Function step-ntk-L2

At the specification level, every element of our router is applied sequentially over all nodes. Function step-ntk1-L2 (Fig. 8) takes as arguments a list of nodes to be processed (ntslist) and the current network state (ntkst). It updates the network state. Function ProcessInputs-L2 applies the input stage to all nodes. As routes have been computed at injection time, the RouteControl module simply "reads" the next hop as the first element of the route. Function RouteControl-L2 performs this "routing" decision at all nodes. After that, function FlowControl-L2 applies the packet switching policy to all nodes. Finally, function ProcessOutputs-L2 applies the output stage at all nodes.
Function step-ntk-L1 extracts the node structures from the list of ports (function ports-nodelist), and calls step-ntk-L2. Function updateNeighbours-L1 simulates the transfer of data from output data signals to input data signals. This function removes the first element of routes.

VI. IMPLEMENTATION – GENOC-L1

Function GeNoC-L1 is the core function of our interpreter for the implementation layer. It takes and returns the same arguments as GeNoC-L2. Its definition is obtained by replacing every occurrence of "L2" with "L1" in Fig. 7. It only injects a packet without appending any additional information.

\[
\text{Fig. 9. Function step-ntk-L1}
\]

Function step-ntk-L1 (Fig. 9) is based on recursive function step-ntkL-L1. The latter takes as arguments a list of nodes to be processed (ntslist) and the current network state (ntkst). It updates the network state. For each node, it applies function router. Function ports-update effectively updates the state of the nodes. Finally, function step-ntk-L1 extracts the node structures from the list of ports (function ports-nodelist), and calls step-ntk-L1. Function updateNeighbours-L1 simulates the transfer of data from output to input signals.

VII. EQUIVALENCE PROOF

The theorem connecting the two models is shown in Fig. 10. Function transform simply removes all routes from extended packets. This theorem states that after the application of transform the lists of arrived packets, the lists of packets still en route in the network, and the final network state produced by GeNoC-L2 equals those produced by GeNoC-L1. The proof in itself is nothing deep. The two interpreters manipulate the same functions. The only difference is in the ordering of these function calls. The difficulties lie in getting the right model definitions and the details of the formal proofs.

Our proof depends on three axioms about the topology and the state generated from it. They basically state that the initial network state is well-formed, e.g., it agrees with the topology.

VIII. CONCLUSION AND FUTURE WORK

We presented the first effort in building a verification methodology of NoCs. We defined two abstractions layers and proved their equivalence. The source routing specification is correctly refined into a distributed routing implementation. A large part of our model and the proof is design-independent. Our plan is to extract the generic part of our proof and obtain a general verification method. We also are working on extending GeNoC-L2 to support global and application-independent properties like functional correctness or deadlock avoidance [15]. We are convinced that the structure of our implementation is similar to the actual structure of RTL designs. One has now to relate our algorithm to the RTL. We plan to investigate the generation RTL code from our models.
