COX-2 polymorphisms $-765G\rightarrow C$ and $-1195A\rightarrow G$ and colorectal cancer risk

Abstract

AIM: To determine the possible modulating effect of the COX-2 polymorphisms, $-765G\rightarrow C$ and $-1195A\rightarrow G$, on the risk of colorectal cancer (CRC) in a Dutch population.

METHODS: This case-control study includes 326 patients with CRC and 369 age- and gender-matched controls. Genotypes of the COX-2 polymorphisms $-765G\rightarrow C$ and $-1195A\rightarrow G$ were determined by polymerase chain reaction-based restriction fragment length polymorphism. COX-2 genotypes and haplotypes were analyzed and odds ratios with 95% confidence intervals were estimated by logistic regression.

RESULTS: The $-765GG$ genotype was associated with an increased risk of developing CRC and the $GG/AC$ haplotype seems to protect against CRC. These findings suggest a modulating role for the COX-2 polymorphisms $-765G\rightarrow C$ and $-1195A\rightarrow G$ in the development of CRC in a Dutch population.

INTRODUCTION

Colorectal cancer (CRC) is a common disease in both men and women. CRC includes cancerous growths in the cecum, colon, sigmoid and rectum. In Western countries, 5% of the population ultimately develop CRC, thus this disease is an important public health issue.[1] CRC is ranked the third most common form of cancer worldwide in terms of incidence.[2] In the Netherlands, CRC is the second most common form of cancer affecting women and the third most common form of cancer affecting men. In 2003 in the Netherlands 9898 new cases of CRC were diagnosed[3].

CRC is usually observed in one of three specific patterns: sporadic, inherited or familial. The sporadic form accounts for approximately 70% in the population and is most common in individuals older than 50 years of age, probably as a result of interactions between low penetrance genes and environmental factors. Fewer than 10% of the population has an inherited predisposition to colon cancer. Inherited colon cancer is usually the result of a single germ line mutation. The third pattern, familial colon cancer, includes those families in which CRC de-
cancer and which are not in a pattern consistent with an inherited syndrome. Up to 25% of all cases of CRC are estimated to fall into this category. \[1\]

Cyclooxygenase (COX), also known as prostaglandin endoperoxidase H synthase, is a modifier gene and key enzyme in the conversion of arachidonic acid into prostaglandins. The COX family consists of two isozymes: COX-1 and COX-2. COX-1 is constitutively expressed in most cell types and is involved in the homeostasis of various physiological functions. COX-1 is well known as the housekeeping gene. COX-2 is an inducible form and its expression can be induced by mitogenic and proinflammatory stimuli. Increased expression of COX-2 is observed in many types of cancers. COX-2 is also associated with many stages of cancer development, e.g., invasion, metastasis, hyperproliferation, transformation and tumor growth. \[4-8\]

Recent studies suggest that single nucleotide polymorphisms (SNPs) in the COX-2 promoter may alter the enzyme function of COX-2 by differential regulation of COX-2 expression. A differential COX-2 expression may influence the risk of the development of gastrointestinal adenocarcinomas, including CRC. \[8-10\]

In a study of African-Americans, an inverse association was found between the Val511Ala polymorphism and the risk of CRC. \[8\] In two studies the promoter polymorphisms -765G→C and -1195A→G were associated with an increased risk of CRC, \[9,10\] whereas Ulrich et al \[11\] reported a reduced risk of CRC associated with the -765G→C polymorphism. The inconsistent results may indicate that the COX-2 polymorphisms -765G→C and -1195A→G may play a role in carcinogenic processes in combination with specific life-style conditions or dependent on the racial composition of a particular population.

The purpose of our study was to determine the possible modulating effect of the COX-2 polymorphisms -765G→C and -1195A→G on the risk of sporadic CRC in a Dutch population. The results of this research will lead to a better understanding on the role of SNPs in the COX-2 promoter in colon cancer carcinogenesis. Such knowledge in future may eventually lead to better preventive measures for CRC.

**MATERIALS AND METHODS**

**Patients and controls**

This case-control study included 326 patients with CRC (59.8% men, 40.2% women) and 369 cancer-free controls (59.1% men, 40.9% women). In the patient group, 31.0% had a proximal tumor and 68.1% had a distal tumor, whereas in 0.9% of cases localization of the tumor was unknown (see legend of Table 1). All subjects were of Caucasian origin with a mean age of 63.7 years and were recruited at Radboud University Nijmegen Medical Center, the Netherlands. The patient and control groups were matched for gender and age. The characteristics of patients and controls are summarized in Table 1.

**Genotyping**

DNA from patients and controls was isolated from whole blood using the Pure Gene DNA isolation kit (Gentra Systems, Minneapolis, MN) and stored at 4°C. Genotypes of the COX-2 -765G→C and -1195A→G polymorphisms were determined by polymerase chain reaction (PCR)-based restriction fragment length polymorphism, according to the method of Zhang et al \[8\].

**Statistical analysis**

The data analysis was performed using SPSS software.

RESULTS

Using cancer-free controls as a reference we tested for an association of the two COX-2 polymorphisms with CRC. The genotype distributions in patients and controls of the two COX-2 polymorphisms investigated are summarized in Table 2. The observed genotype distributions for the -765G→C and -1195A→G polymorphisms in patients with CRC and controls were in accordance with the Hardy-Weinberg equilibrium, with P-values of 0.19 and 0.99 for patients with CRC and 0.24 and 0.46 for controls, respectively. When both polymorphisms were investigated separately, there was no significant difference in the -765G→C or -1195A→G allele frequency between the patient and control group. However, the -765GG genotype was more frequent in patients than in controls (OR 1.45; 95% CI, 1.03-2.04). There was no significant difference in the genotype distribution of the -1195A→G polymorphism among patients and controls.

Next, the potential association of genotype distribution of the two COX-2 polymorphisms with tumor localization was investigated. We distinguished proximal and distal tumor localization. Proximal included the cecum, colon ascendens and colon transversum and distal included the rectum, sigmoid, colon descendens and flexura lienalis. No association between the -765G→C and -1195A→G polymorphisms and tumor localization was detected.

Also no association of the genotype distribution of the -765G→C and -1195A→G polymorphisms in the patient group was found with gender and age.

Based on the two polymorphisms tested, a haplotype analysis was performed in the two populations studied and seven haplotypes could be distinguished (Table 3). A significant difference between the COX-2 haplotypes was observed. The GG/AC haplotype was less frequent in patients (OR, 0.44; 95% CI, 0.22-0.85). When the AC, AG and GG haplotypes were investigated separately, the AC haplotype tended to occur less frequently in patients than in controls (OR, 0.75; 95% CI, 0.57-1.06).

DISCUSSION

The COX-2 protein was detected in 70% of all colorectal cancer tissues. In adjacent normal colorectal tissue in the same slide the COX-2 protein was not observed. These results suggest that increased expression of COX-2 is associated with CRC[10]. SNPs in the COX-2 promoter may alter the enzyme activity of COX-2 by differential regulation of COX-2 expression, which may influence the risk of the development of CRC[8-9]. It has been recently demonstrated that the polymorphisms -765G→C and -1195A→G may have a functional effect on COX-2 expression and enzyme activity[7-9]. Both the -765G→C and -1195A→G polymorphisms were shown to display a lower COX-2 promoter activity, which may result in a lower expression of the COX-2 enzyme[8,13].

We investigated the potential association of the COX-2 polymorphisms -765G→C and -1195A→G and the risk of developing CRC, and found that the -765GG genotype was present more often in patients than in controls. As demonstrated by Zhang et al[8], the reporter gene expression driven by the -765G-containing COX-2 promoter was higher as compared to the -765C-containing counterpart. This indeed could mean a higher COX-2 expression in -765GG individuals.

A study in American Caucasians reported a reduced risk of colorectal adenomas in individuals bearing the -765GG genotype, but this lower risk was found only among users of non-steroidal antiinflammatory drugs (NSAIDs). In addition, a lower risk of adenoma among -765CC genotypes was found only in non-users of NSAIDs[11]. Zhang et al[8] and Tan et al[9] reported that the -765GG genotype was associated with an increased...
risk of esophageal squamous cell carcinoma (ESCC) and CRC, in Chinese populations. The findings of Tan et al\(^5\) and Zhang et al\(^{14}\) seem in contrast with our results, since we found a reduced risk of CRC with the -765GC genotype. However, racial differences in the study populations may explain these apparent contradictory results, since the distribution of the COX-2 polymorphisms studied here differs considerably between the Chinese and Dutch study populations. The genotype frequencies found in our Dutch patients with CRC for the -765G→C and -1195A→G polymorphisms were: 73.9% GG, 23.0% GC, 3.1% CC and 65.3% AA, 31.0% GA and 3.7% GG, respectively. Zhang et al\(^3\) in a Chinese population reported genotype frequencies of 90.6% GG, 9.4% GC, 0% CC and 30.5% AA, 52.9% GA and 16.6% GG. Tan et al\(^3\) in Chinese patients with CRC recently reported approximately the same genotype frequencies as Zhang et al\(^3\): 91.6% GG, 8.4% GC, 0% CC and 34.5% AA, 49.4% GA and 16.1% GG. These findings suggest that ethnic differences in genotype frequencies of COX-2 polymorphisms may have a significantly different modulating effect on disease phenotypes in different ethnic populations.

According to Zhang et al\(^3\) and Tan et al\(^{14}\) in a Chinese population, the -1195GA and -1195AA genotypes were associated with an increased risk of ESCC and CRC, respectively. This again is not in line with our findings, since we could not demonstrate a significant difference in the allele distribution of the -1195A→G polymorphism between our Dutch patients with CRC and controls.

We also investigated the potential association of the genotype distributions of the -1195A→G and -765G→C polymorphisms with tumor localization. No association between the two polymorphisms and tumor localization was found, which is in accordance with the results of Tan et al\(^{14}\) who found a very similar distribution of both COX-2 genotypes in patients with colon (n = 403) or rectal (n = 597) cancer.

The COX-2 GG/AC haplotype (-1195G-765C/-1195A-765C) was found to be present less frequently in patients. When the AC, AG and GG haplotypes were investigated separately, the AC haplotype tended to be less frequently present in patients with CRC than in controls (OR, AG/AC 0.78; 95% CI, 0.57-1.06). This is in line with the findings of Zhang et al\(^3\) who demonstrated that the luciferase expression of the AG constructs was higher than the expression of the AC constructs, suggesting that the AC haplotype was associated with a lower COX-2 expression and a decreased risk of CRC.

However, Zhang et al\(^3\), Tan et al\(^{14}\) and Moons et al\(^{14}\) found an association of the AC haplotype with an increased risk of ESCC, CRC and esophageal adenocarcinoma (EAC). These findings are in contrast with our results, as described above. In addition, the predicted expression levels of the COX-2 protein are higher in AG versus AC haplotype individuals, according to Zhang et al\(^3\), which is not in agreement with the hypothesis that high expression of COX-2 is a risk factor for colorectal or esophageal carcinoma. It should be noted however that haplotype frequencies of AC are very low in the patient and control populations studied by Zhang et al\(^3\) and Tan et al\(^{14}\), being 4.5% vs 1.6% and 3.8% vs 1.8%, respectively, compared to 21.2% vs 32.6% in our study. In the study of Moons et al\(^{14}\) the AC haplotype occurred in 25.0% of the total study population, who were patients with esophageal adenocarcinoma, Barrett’s esophagus and reflux esophagitis, a proportion which is very close to our data. In the study of Moons et al\(^{14}\) unfortunately no cancer-free controls were included, but patients with Barrett’s esophagus or reflux esophagitis were used as controls, both of which would confer a risk of esophageal adenocarcinoma.

In summary, we found a significant difference in the -765G→C polymorphism distribution between the patients with CRC and the control group; the -765GG genotype was associated with an increased risk for CRC. The GG/AC haplotype was found less frequently in patients with CRC and may be associated with a reduced risk of CRC. These findings suggest a modulating role for the COX-2 polymorphisms -1195A→G and -765G→C in the development of CRC in a Dutch population.
