Abstract

Immunoglobulin A (IgA) secretion by plasma cells in the immune system is critical for protecting the host from environmental and microbial infections. However, the molecular mechanisms underlying the generation of IgA+ plasma cells remain poorly understood. Here, we report that the B cell–expressed tetraspanin protein CD37 inhibits IgA immune responses in vivo. CD37-deficient (CD37−/−) mice exhibit a 15-fold increased level of IgA in serum and significantly elevated numbers of IgA+ plasma cells in spleen, mucosal-associated lymphoid tissue, as well as bone marrow. Analyses of bone marrow chimeric mice revealed that CD37–deficiency on B cells was directly responsible for the increased IgA production. We identified high local interleukin-6 (IL-6) production in germinal centers of CD37−/− mice after immunization. Notably, neutralizing IL-6 in vivo reversed the increased IgA response in CD37−/− mice. To demonstrate the importance of CD37—which can associate with the pattern-recognition receptor dectin-1—in immunity to infection, CD37−/− mice were exposed to Candida albicans. We report that CD37−/− mice are evidently better protected from infection than wild-type (WT) mice, which was accompanied by increased IL-6 levels and C. albicans–specific IgA antibodies. Importantly, adoptive transfer of CD37−/− serum mediated protection in WT mice and the underlying mechanism involved direct neutralization of fungal cells by IgA. Taken together, tetraspanin protein CD37 inhibits IgA responses and regulates the anti-fungal immune response.

Introduction

Plasma cells (non-dividing antibody-secreting cells, ASC) are terminally differentiated B cells that are central to humoral immunity. Both mucosal and systemic immune responses to infection can induce IgA+ plasma cell formation, resulting in production of secretory and serum IgA respectively. In both pathways, isotype class-switching in B cells is tightly regulated by the cytokine-milieu. While it is believed that interleukin-6 (IL-6), originally described as a B-cell stimulating factor [1], stimulates plasma cell differentiation and promotes IgA responses in vivo [2], the molecular mechanisms underlying the development of IgA-secreting plasma cells remain poorly understood. In particular, detailed knowledge about proteins in the B cell membrane that control this process is lacking.

IgA-secreting plasma cells are predominantly found in the mucosal-associated lymphoid system (MALT) and bone marrow. During the mucosal immune response, intestinal dendritic cells present mucosal antigen to CD4+ T cells in Peyer’s patches, or present antigen directly to B1 cells in a T cell-independent manner [3,4]. This leads to the local production of secretory IgA, which is important in neutralizing intestinal microbes and controlling gut homeostasis. Secondly, systemic immune responses to T cell-dependent antigens lead to the development of germinal centers (GC) in spleen and peripheral lymph nodes that are the origin of long-lived plasma cells that produce high affinity IgG and IgA antibodies in serum [5–7]. Recent studies have underlined the importance of local production of B cell stimuli (cytokines, TLR ligands) in inducing IgA production during the humoral immune response [3,8], including IL-6 that promotes the generation of IgA-secreting plasma cells [2,3].

Tetraspanins, or transmembrane-four superfamily proteins, are implicated in organizing (immuno)-receptors, integrins, and signaling molecules into functional membrane complexes (tetraspanin microdomains) [9–12]. Consequently, tetraspanins are important in fundamental cellular processes including migration, proliferation, differentiation, and—with deregulated- cancer [13]. CD37 is expressed exclusively on cells of the immune system, in
Author Summary

Antibody, or immunoglobulin (Ig), production by plasma cells in the immune system is important for protecting the host from microbial infections. IgA is the most abundant antibody isotype produced in the body. However, the molecular mechanisms underlying the generation of IgA-producing plasma cells remain poorly understood. We now report that the B cell–expressed protein CD37 regulates IgA immune responses, both in steady-state conditions and during infection. We found highly increased levels of IgA in serum and elevated numbers of IgA+ plasma cells in lymphoid tissue of mice that are deficient for CD37 (CD37−/− mice). To demonstrate the importance of CD37 in immunity to infection, CD37−/− mice were exposed to the fungus Candida albicans. C. albicans can cause systemic infection with high mortality in immunocompromised patients. We demonstrate that CD37−/− mice are evidently better protected from infection than wild-type mice, which was dependent on C. albicans–specific IgA antibodies. The underlying mechanism involved direct neutralization of fungal cells by IgA. In summary, the B cell–expressed protein CD37 inhibits IgA responses and anti-fungal immunity. This study may contribute to the development of novel immunotherapeutic approaches for invasive fungal disease.

Increased formation of IgA–secreting plasma cells in CD37−/− mice

The high IgA titers in serum of CD37−/− mice suggest an enhanced generation of IgA-secreting plasma cells. To determine if this was the case, spleens, bone marrow, and mucosal-associated lymphoid tissue from immunized mice were examined for the frequency of NP-specific IgA-ASC using ELISPOT assays. In line with IgA levels in serum, the numbers of IgA-ASC were increased in spleen of CD37−/− mice compared to control WT mice at day 14 following immunization (Figure 2A). This observation was confirmed by immunohistochemical analysis (Figure 2B). High numbers of IgA+ cells were present in GC and white pulp area in spleens of immunized CD37−/− mice, whereas in spleens of WT mice IgA+ cells were very rarely detected. CD138 stainings confirmed that the IgA+ cells in CD37−/− spleens were indeed plasma cells (Figure 2C). Since IgA-ASC are known to migrate preferentially to the MALT using specific gut-homing receptors [21], Peyer’s patches and mesenteric lymph nodes of immunized CD37−/− mice were analyzed for the presence of NP-specific IgA-ASC. Both the morphology and organization of mesenteric lymph nodes (Figure 2D) and Peyer’s patches (Figure 2E) of CD37−/− mice were comparable to WT mice, although CD37−/− Peyer’s patches were slightly increased in size. The percentage of IgA+ NP-specific plasma cells was increased in MALT of immunized CD37−/− mice compared to WT controls (Figure 2F), demonstrating that IgA-ASC generated in CD37−/− spleens preferentially homed to the MALT rather than to the bone marrow. IgG1+ NP-specific plasma cells were hardly detected in MALT of CD37−/− and WT mice as expected. Taken together, CD37−/− mice possess increased generation of antigen-specific IgA+ plasma cells after immunization.

Elevated IgA responses in CD37−/− mice are dependent on IL-6

IL-6 is a cytokine that has been implicated in promoting the generation of IgA-secreting plasma cells [2,3]. Moreover, we have recently shown that signals transduced through the CD37
molecular partner, dectin-1, lead to an elevated production of IL-6 by CD37
2/2 cells [17]. Consequently, we examined whether a
dysregulation of IL-6 production in immunized CD37
2/2 mice may underlie the excess production of IgA. We first examined the
expression of IL-6 in the germinal centers (GC) of immunized mice by immunohistochemistry. We readily detected IL-6
Figure 2. Increased formation of IgA–secreting plasma cells in CD37−/− mice. (A) The frequency of high affinity NP-specific IgA–ASC was assessed in CD37−/− (white) and WT (black) spleen and bone marrow by ELISPOT at d 14 and 35 of the immune response. Non-immunized mice are...
expression in the GC area of spleens of immunized CD37−/− mice was stimulated with NP-KLH in vitro in the absence or presence of neutralizing IL-6 antibodies. Figure 3B shows increased IgA production by CD37−/− cultures compared to WT cells as expected. Blocking IL-6 resulted in substantially reduced IgA production by CD37−/− cells, which supported our hypothesis that the mechanism underlying the elevated IgA responses in CD37−/− mice is controlled at the level of IL-6. WT and CD37−/− cultures produced 1900 vs. 5500 pg/ml IgA respectively, which decreased to 500 vs. 2000 pg/ml in the presence of neutralizing IL-6 antibodies. We also established that purified CD37−/− splenic B cells were capable of autocrine IL-6 production upon restimulation in vitro using intracellular cytokine stainings (data not shown).

To prove that increased IgA production in CD37−/− mice was indeed dependent on IL-6 in vivo, we neutralized IL-6 in WT and CD37−/− mice during immunizations using blocking antibodies. Serum was analyzed for the presence of high affinity (anti-NP) IgA antibodies at different days after immunization. Evidently, IL-6 neutralization reversed the production of high IgA levels in CD37−/− serum (Figure 3C, lef), demonstrating the importance of IL-6 in IgA plasma cell development in CD37−/− mice. Only 25% of the CD37−/− mice produced NP-specific IgA titers after treatment with anti-IL-6 antibodies, compared to 100% of isotype control-treated CD37−/− mice 14 days after immunization (Figure 3C, right). IgA formation by WT mice (with or without anti-IL-6) was below the level of detection (not shown). Our findings are in accordance with observations made in IL-6-deficient mice that exhibit impaired antibody production during systemic immune responses [23, 25]. Mucosal IgA responses were reported to be significantly impaired or unaltered in IL-6-deficient mice dependent on the model of immunization used [22, 23, 25, 26]. Moreover, IL-6 polymorphisms were recently reported to be associated with IgA-deficiency in patients [27]. Since IL-6 is crucial for the induction of already-committed (surface IgA+) B cells to become IgA-secreting plasma cells [2], our data suggest that CD37 is directly implicated in the inhibition of the late-stage development of IgA plasma cells, i.e. at the level of terminal B cell differentiation. Taken together, we established that high IL-6 levels directly relate to the increased IgA production in CD37−/− mice.

IgA production during fungal infection in CD37-deficient mice

Given that IgA contributes to protecting the host from microbial infections, we hypothesized that CD37-deficiency may have important implications for the outcome of infectious diseases. We have recently demonstrated that CD37 interacts with the C-type lectin dectin-1 [17], a β-glucan receptor that is required for effective immunity to fungal infections [20, 29]. Therefore, the CD37-deficient immune response during Candida albicans infection was explored. C. albicans normally colonizes the mucosa without causing disease, but can cause systemic infection with high mortality in immunocompromised patients [30, 31]. In particular, the incidence of invasive C. albicans infections is high among cancer patients [32–34].

CD37−/− and WT mice were infected with C. albicans and IL-6 production by CD37−/− and WT splenocytes was studied upon restimulation with fungal antigens. CD37−/− splenocytes produced increased levels of IL-6 compared to WT cells upon exposure to either live or heat-killed C. albicans, or the fungal cell wall extract zymosan both 3 and 7 days after infection (Figure 4A). Blocking dectin-1 with antibody 2A11 inhibited IL-6 production by both WT and CD37−/− splenocytes stimulated with C. albicans or the dectin-1 ligand curdlan (Figure S1), showing that IL-6 production is dependent on dectin-1. As such, CD37 controls dectin-1-mediated IL-6 production, possibly by recruiting dectin-1 into tetraspanin microdomains that may alter signal transduction pathways and subsequent cytokine profiles. In line with our findings, IL-6-deficient mice are more susceptible to C. albicans and A. fumigatus infection, which is related to decreased neutrophil effector activity, impaired Th1-mediated immune responses [25], and defective Th17 responses [35]. Studying Th2/Th1/Th17 cytokine production by CD37−/− splenocytes revealed that IL-10 production was comparable between CD37−/− and WT splenocytes, and γIFN production was low but increased by CD37−/− cells 3 days after infection (Figure 4A). The role of IL-6 in inducing Th17 responses is well established in mice. Accordingly, we observed significantly increased IL-17 production by CD37−/− splenocytes upon C. albicans stimulation (Figure 4A). Th17 cells have been implicated as an important effector mechanism against C. albicans infection [36, 37], although IL-17 may also impair anti-fungal immunity under certain conditions [38, 39].

Next, the development of fungal-specific IgA antibodies in CD37−/− and WT mice exposed to C. albicans was analyzed. WT mice did not generate a detectable IgA response after C. albicans infection. In contrast, all CD37−/− mice exhibited high titers of IgA antibodies specific for C. albicans and zymosan in their serum (Figure 4B). C. albicans-specific IgG was not detected in serum of WT and CD37−/− mice 7 days after infection (not shown). Finally, we investigated the role of tetraspanin CD37 in the outcome of infectious disease. WT and CD37−/− mice were systemically infected with C. albicans yeasts, and kidneys were analyzed for the outgrowth of viable C. albicans after 1 and 7 days. CD37−/− mice exhibited significantly decreased susceptibility to infection and reduced fungal outgrowth in their kidneys—the main target organ for C. albicans - 7 days after infection when compared to WT mice (Figure 4C, left). Histology revealed major infection areas with abscesses and hyphal infiltration in WT kidneys. In contrast, morphology of kidneys of CD37−/− mice looked
Figure 3. Increased IgA production after immunization in CD37−/− mice is dependent on IL-6. (A) Immunohistochemical analysis of spleens from CD37−/− and WT mice 14 d after NP-KLH immunization. Germinal centers (identified in serial sections by PNA staining) are indicated in the B cell follicles. Immunized WT mice have non-detectable levels of IL-6 in spleens (left). In contrast, B cell follicles in spleens of immunized CD37−/− mice are clearly positive for IL-6 (red) in the GC area (right). Spleens of non-immunized mice (WT and CD37−/−) were negative for IL-6 staining (not shown). Scale bar is 50 μm. (B) Effect of neutralizing anti–IL-6 during ex vivo restimulation. Splenocytes from WT and CD37−/− mice were prepared 14 d after NP-KLH immunization, and stimulated in vitro with NP-KLH (1 μg/ml) in the absence or presence of anti–IL-6. Supernatants were collected after 48 h, and assayed for IgA production by ELISA (expressed in arbitrary units). Asterisk indicates significant difference (*p<0.002). (C) IL-6 was neutralized in WT and CD37−/− mice during immunizations using blocking IL-6 antibodies (as described in Materials and methods). High affinity NP-specific IgA was assayed in serum of CD37−/− mice treated with anti–IL-6 (black) or control antibody (white) (left). Antibody titer is expressed in arbitrary units and represented as mean±SEM (n=6). Asterisks indicate significant difference as per: *p<0.04. Histogram shows percentage of CD37−/− mice with high IgA anti-NP3 levels (above 106 background level) in serum after treatment with anti–IL-6 (black) compared to control treated CD37−/− mice (white) at indicated days after immunization (right). Similar results were obtained for total NP-specific antibody (against NP20-BSA).

normal with no mycelial structures and presence of leukocyte infiltrates (Figure 4C, right). Next, we evaluated survival of WT and CD37−/− mice after lethal fungal infection. The absence of CD37 resulted in prolonged survival and decreased mortality after lethal candidiasis (Figure 4D), further emphasizing the importance of CD37 in regulating anti-fungal immunity.

In order to get more insight into the underlying mechanism, CD37−/− serum was analyzed for fungal opsonization and/or neutralizing capacity. IgA-mediated phagocytosis through Fc alpha receptor CD89 is well-established in humans [40,41], in whom serum IgA is mostly monomeric. In mice, serum IgA is predominantly dimeric/polymeric and it is currently unknown whether the murine Fcα/μ receptor is effective in clearing IgA-opsonized pathogens [42]. We observed similar uptake of C. albicans by GR-1+ neutrophils in the presence of infected WT or CD37−/− serum of infected mice (Figure 5A). Serum heat-inactivation inhibited C. albicans uptake, demonstrating that the phagocytosis was mainly complement-mediated and not dependent on IgA. Also, the increase in GR-1-expressing cells in blood after C. albicans infection was comparable between WT and CD37−/− mice.

Figure 4. CD37−/− mice are protected against C. albicans infection. CD37−/− and WT mice (n=5) were systemically infected with 1×10⁵ C. albicans. (A) Spleens were removed 3 or 7 d after infection and splenocytes were stimulated with live, heat-killed C. albicans yeasts, zymosan (E:T ratio 2:1) for 48 h, after which IL-6, IL-10, IL-17, and γIFN in supernatants were measured by ELISA. Asterisks indicate significant difference as per: *p<0.05 and **p<0.002. (B) Serum of CD37−/− and WT mice was analyzed for the presence of IgA antibodies reactive with C. albicans yeast (left) or zymosan (right) by flow cytometry as described in Materials and methods. Serum of non-infected mice is shown as control. Asterisks indicate significant difference as per: *p<0.005. (C) left: Subgroups of five or six animals were sacrificed on d 1 or 7, and kidneys were analyzed for the number of viable Candida cells (expressed as log CFUg⁻¹ tissue). Horizontal bars represent mean. Asterisks indicate significant difference as per: *p<0.0005. Right: Histology of kidneys from WT and CD37−/− mice 7 d after infection. Note the major infection area and infiltrating hyphae in WT kidneys. (D) Survival of WT and CD37−/− mice (n=6) was assessed after intravenous injection of lethal dose of 5×10⁵ CFU C. albicans.

doi:10.1371/journal.ppat.1000338.g004

Figure 5. Adoptive transfer of CD37−/− serum increases resistance of WT mice to fungal infection. (A) Percentage of GR-1⁺ blood leukocytes that phagocytosed FITC-labeled C. albicans in the absence or presence of serum from infected WT or CD37−/− mice for various time points at 37° C was quantified by flow cytometry. Sera were heat-inactivated (56° C for 30 min) to inactivate complement (left). In addition, uptake in the presence of WT or CD37−/− serum was analyzed by fluorescence light microscopy (right; data shown for 30-min. incubation). Bar represents 10 μm. (B) C. albicans was incubated in the absence or presence of 20% serum (from infected WT or CD37−/− mice) or 20% IgA–depleted serum and growth (CFU) was assessed. Asterisks indicate significant difference as per: p<0.005. (C) WT mice (n=5) were systemically infected with 1×10⁵ C. albicans and untreated, or treated with either pooled CD37−/− serum containing high levels of fungal-specific IgA, or IgA-depleted CD37−/− serum. Kidneys were analyzed for the number of viable Candida cells (expressed as log CFUg⁻¹ tissue) 7 d after infection. Horizontal bars represents mean. Asterisks indicate significant difference as per: p<0.05.

Immunity.

Next, we investigated whether serum IgA of CD37−/− mice could directly neutralize fungal cells. C. albicans was grown in the absence or presence of WT and CD37−/− serum of infected mice and viability was assessed by classical plate assays. CD37−/− serum significantly inhibited C. albicans growth in contrast to WT serum (Figure 3B). To demonstrate that the growth inhibition was due to fungal-specific IgA, CD37−/− serum was depleted for IgA. Serum deprived from IgA abrogated the effect, and C. albicans growth was comparable between WT and CD37−/− serum. From these findings we conclude that IgA in CD37−/− serum directly neutralizes C. albicans and may thereby prevent dissemination in vivo.

To test this hypothesis, WT mice were infected and treated with pooled CD37−/− serum containing high levels of IgA anti-C. albicans. We observed that WT mice were protected from fungal disease by CD37−/− serum treatment (Figure 5C). Importantly, the resistance was abrogated when IgA was depleted from CD37−/− serum, demonstrating that the passive transfer of resistance to candidiasis in CD37−/− mice is dependent on IgA. Although the elevated IL-6-IL-17 response may also contribute to increased anti-fungal effector activity in CD37−/− mice (Figure 4A), our passive transfer data clearly show that C. albicans-specific IgA alone is sufficient to confer protection against invasive fungal disease. Whilst several studies have alluded to a role for the development of protective anti-fungal antibodies in experimental candidiasis [43,44], this is—to the best of our knowledge—the first description of an important role for IgA in protection against systemic candidiasis. These studies also highlight the non-redundant role of the tetraspanin CD37, as CD37-deficiency stimulates anti-fungal immunity even in the presence of other tetraspanins. The results of this study may stimulate the development of novel immunotherapeutic strategies for invasive fungal disease that are urgently warranted [33].

In summary, we reveal a unique role for the tetraspanin CD37 in the humoral immune response; CD37 is a negative regulator of IgA plasma cell generation in vivo and this role is critically dependent on IL-6. Moreover, this is the first demonstration that tetraspanins may control the immune-mediated defense against fungal pathogens. This study increases our understanding of molecular mechanisms underlying the formation of IgA-secreting plasma cells and may contribute to better insight into anti-fungal immunity.

Materials and Methods

Quantitative RT–PCR

Marine CD37 expression was analyzed at the mRNA level by quantitative RT–PCR due to unavailability of anti-mouse CD37 antibodies. Total RNA was extracted from WT and CD37−/− leukocyte populations (purified by MACS sorting, Miltenyi Biotec) using Trizol (Invitrogen) and transcribed into cDNA using random hexamer primers (Amersham) and Superscript II RT (Invitrogen). cDNA was amplified using SYBR Green PCR mastermix (Applied Biosystems) with mouse CD37 primers (5′GTCCTTTGGTTGGTGGTTGTGCTTT and 5′GAGACCGCGCAGCTCTTTTAG). The amount of CD37 mRNA expression was normalized to the housekeeping gene PBGD.

Human CD37 expression

Peripheral blood lymphocytes were stained with anti-CD37 (clone WR17, Serotec) and processed for FACS analysis as previously described [17]. CD37 staining in tissue was performed on frozen sections (6 μm) of spleen and lymph node that were fixed in acetone for 10 minutes at −20°C. Slides were blocked (5% horse serum) and stained with anti-CD37 or mlgG2a isotype control. Horse anti-mouse-biotin (Molecular Probes) was used as secondary Ab, and staining was revealed using SA-alkaline phosphatase labeling kit (Vector Laboratories) with Fast Red substrate. Slides were counterstained with Meyer’s hematoxylin.

Mice

CD37−/− mice were generated by homologous recombination [14] and backcrossed 10 times to the C57BL/6J background. Age and sex-matched C57BL/6J wild type (WT) mice were obtained from the Walter and Eliza Hall Institute (Melbourne, Victoria, Australia) and Charles River (France). CD37−/− mice were bred at the Burnet Institute Austin Campus (Heidelberg, Victoria, Australia) and the Central Animal Laboratory (Radboud University Nijmegen, The Netherlands). μMT (B cell-deficient) mice [45] were bred at the Walter and Eliza Hall Institute. Mice were used at 8–12 weeks of age. Animal studies were approved by animal ethics committee of the Austin&Repatriation Medical Centre, and the Nijmegen Animal Experiments Committee.

Immunization

WT and CD37−/− (n = 6) were injected intraperitoneally with 100 μg of NP (4-hydroxy-3-nitrophenylacetate) coupled to Keyhole Limpet Hemocyanin (KLH) (NP17:KLH, conjugation ratio, 1:7:1) precipitated in alum. Mice were bled and sera collected at days 7, 14, 21 and 35 post-immunization. Lymphoid organs (spleens, bone marrow, mesenteric lymph nodes, and Peyer’s patches) were frozen for immunohistochemistry or processed for FACS analysis.

Detection of Ag-specific immunoglobulin and antibody-secreting cells

Basal immunoglobulin levels in serum of non-immunized mice (n = 9) were determined by ELISA using goat anti-mouse IgG/IgA/IgM (BD-Pharmingen). Ig standards were purchased from BD. Levels of NP-specific antibodies in serum after immunization were assayed by ELISA using plates coated with 20 μg/mL of either NP20-BSA or NP3-BSA to detect total and high affinity anti-NP antibody, respectively. The frequency of total and high affinity NP-specific ASC in spleen and bone marrow was determined by ELISPOT as described [20,46], again using NP20-BSA and NP3-BSA for antibody capture.

Immunohistochemistry

Spleens, mesenteric lymph nodes and Peyer’s patches taken from mice before and after immunization were embedded in OCT. Frozen sections (6 μm) were fixed in acetone for 10 min. at −20°C. Slides were blocked (5% goat serum) and stained with anti-IgA, anti-IgG1, anti-IL-6, anti-CD138, anti-CD45R (BD, Australia) and the Central Animal Laboratory (Radboud University Nijmegen, The Netherlands). μMT (B cell-deficient) mice [45] were bred at the Walter and Eliza Hall Institute. Mice were used at 8–12 weeks of age. Animal studies were approved by animal ethics committee of the Austin&Repatriation Medical Centre, and the Nijmegen Animal Experiments Committee.

Reconstitution experiments

Bone marrow chimeras were generated as previously described [47]. Briefly, 107 (CD37−/− or WT) and μMT (CD37+ bone marrow cells were injected intravenously into sublethally irradiated C57Bl/6J recipient mice at a ratio of 4 parts μMT to 1 part WT.
or CD37−/− bone marrow as a source for B cells. This created WT mice and mice with a CD37-deficient B cell compartment (referred to as chimeric CD37−/− mice). Six weeks after reconstitution, heparinized blood was obtained from chimeric mice and reconstitution of all major leukocyte populations was monitored by flow cytometry, using the antibodies against: PE-conjugated 1D3-PE (CD19, BD-Pharmingen), PE-conjugated RB6-8C5-PE (GR-1, BD-Pharmingen), Cy3-conjugated KT3.1 (CD3, made in house), PE-conjugated F4/80 (BD-Pharmingen), and FITC-conjugated M1/70 (CD11b, made in house). 2 weeks thereafter, mice (n = 7) were immunized with NP-KLH as described above. Sera were collected 35 days after immunization and analyzed for presence of NP-specific antibodies by ELISA.

**Ex vivo restimulation experiments**

Splenocytes were prepared from WT and CD37−/− mice 14 days after NP-KLH immunization. Cells were stimulated with NP-KLH (1 μg/ml) in the absence or presence of 5 μg/ml (azide- and LPS-free) neutralizing anti-IL-6 MP5-20F3 or isotype control; 60 μg intraperitoneally at day 0, and 60 μg intravenously 7 days after immunization. Mice were bled and sera collected at days 7, 14, 21 and 35 post-immunization. Lymphoid organs (spleens, bone marrow, mesenteric lymph nodes, and Peyer’s patches) were frozen in OCT for immunohistochemistry or processed for FACS analysis.

**IL-6 neutralization in vivo**

WT and CD37−/− mice (n = 6) were immunized with NP-KLH as described above. Mice received 2 injections of neutralizing (azide- and LPS-free) anti-IL-6 MP5-20F3 or isotype control; 60 μg intraperitoneally at day 0, and 60 μg intravenously 7 days after immunization. Mice were bled and sera collected at days 7, 14, 21 and 35 post-immunization. Lymphoid organs (spleens, bone marrow, mesenteric lymph nodes, and Peyer’s patches) were frozen in OCT for immunohistochemistry or processed for FACS analysis.

**Candida albicans infection protocols**

*C. albicans* ATCC MYA-3573 (UC820), a well-described clinical strain [48], was injected intravenously (1 × 10^5 colony-forming units (CFU), in 100 μL sterile pyrogen-free saline) in CD37−/− and WT mice. Blood (50 μL) was collected at different time points after infection and stained with GR-1-PE to identify neutrophils by flow cytometry. Subgroups of five or six animals were sacrificed on day 1 or 7, and kidneys were removed aseptically, weighed and homogenized in sterile saline in a tissue grinder. The number of viable Candida cells in the tissues was determined by plating serial dilutions on Sabouraud dextrose agar plates. Colony-forming units were counted after 24 h of incubation at 37°C, and expressed as log CFU/g tissue. Alternatively, kidneys were embedded in OCT, and frozen sections (6 μm) were stained with periodic acid-Schiff to identify *C. albicans* by histology. In adoptive transfer experiments, WT mice (n = 5) received 1 × 10^6 CFU *C. albicans* intravenously (in 100 μL sterile pyrogen-free saline) with 20% pooled serum of infected WT or CD37−/− mice; collected 7 days after infection) or 20% IgA-depleted serum. Viability was assessed after shaking for 5 h at 37°C by plating serial dilutions on Sabouraud dextrose agar plates.

**Statistical analyses**

Data are presented as mean±SEM. Statistical differences were determined using the unpaired Student’s t-test. Significance was accepted at the p<0.05 level.

**Accession/ID numbers**

**Supporting Information**

**Figure S1** IL-6 production by WT and CD37−/− splenocytes stimulated by *C. albicans* is dependent on dectin-1. Splenocytes were removed from CD37−/− and WT mice 7 d after infection (1 × 10^5 CFU *C. albicans*) and restimulated with heat-killed *C. albicans* (E:T ratio 2:1) or the dectin-1 ligand Curdlan (100 μg/ml) for 48 h, after which IL-6 in supernatants were measured by ELISA. Antibody 2A11 was added during stimulations (10 μg/ml) to block dectin-1.

**Figure S2** Normal increase of GR-1-positive cells in blood of CD37−/− mice. Granulopoiesis in WT and CD37−/− mice (n = 5) systemically infected with 1 × 10^6 CFU *C. albicans*. Percentage ELISA assays (Biosource, Camarillo, CA; detection limit 16 pg/ml, according to the instructions of the manufacturer. In dectin-1 blocking studies, antibody 2A11 (10 μg/ml) was added during stimulations as described [17]. Curdlan is a specific dectin-1 ligand with no TLR2- or TLR4-stimulating properties [49].

**Detection of anti-*Candida* IgA antibodies in mice**

Serum of CD37−/− and WT mice (n = 5) was collected 7 days after *C. albicans* infection, and different dilutions were incubated with 1 × 10^5 Candida or 1 × 10^5 zymosan particles for 30 min. at 4°C. After washing twice in saline, *Candida* particles were incubated with biotinylated anti-mouse IgA (BD-Pharmingen) followed by SA-CY5 (Invitrogen), and analyzed by flow cytometry. Serum of non-infected mice was used as control.

**IgA depletion of serum**

Streptavidin-coated 2 μm microspheres (Polysciences, PA) were incubated with biotinylated anti-mouse IgA (BD Biosciences) according to the instructions of the manufacturer. Sera of WT and CD37−/− mice (n = 4) were collected 7 days after *C. albicans* infection, pooled, and incubated with 100 × 10^6 anti-IgA coated microspheres (1 h at RT, shaking).
CD37 Inhibits IgA Responses

Dectin-1 is required for beta-glucan recognition and control of fungal infection.

Dectin-1 is required for host defense against Pneumocystis carinii but not against Candida albicans.

Atributable mortality of nosocomial candidemia, revisited.
