Outcome Prediction in Mild Traumatic Brain Injury:
Age and Clinical Variables Are Stronger
Predictors than CT Abnormalities

Bram Jacobs,1 Tjemme Beems,2 Maja Stulemeijer,1 Arie B. van Vugt,3 Ton M. van der Vliet,4 George F. Borm,5 and Pieter E. Vos1

Abstract
Mild traumatic brain injury (mTBI) is a common heterogeneous neurological disorder with a wide range of possible clinical outcomes. Accurate prediction of outcome is desirable for optimal treatment. This study aimed both to identify the demographic, clinical, and computed tomographic (CT) characteristics associated with unfavorable outcome at 6 months after mTBI, and to design a prediction model for application in daily practice. All consecutive mTBI patients (Glasgow Coma Scale [GCS] score: 13–15) admitted to our hospital who were age 16 or older were included during an 8-year period as part of the prospective Radboud University Brain Injury Cohort Study (RUBICS). Outcome was assessed at 6 months post-trauma using the Glasgow Outcome Scale-Extended (GOSE), dichotomized into unfavorable (GOSE score 1–6) and favorable (GOSE score 7–8) outcome groups. The predictive value of several variables was determined using multivariate binary logistic regression analysis. We included 2784 mTBI patients and found CT abnormalities in 20.7% of the 1999 patients that underwent a head CT. Age, extracranial injuries, and day-of-injury alcohol intoxication proved to be the strongest outcome predictors. The presence of facial fractures and the number of hemorrhagic contusions emerged as CT predictors. Furthermore, we showed that the predictive value of a scheme based on a modified Injury Severity Score (ISS), alcohol intoxication, and age equalled the value of one that also included CT characteristics. In fact, it exceeded one that was based on CT characteristics alone. We conclude that, although valuable for the identification of the individual mTBI patient at risk for deterioration and eventual neurosurgical intervention, CT characteristics are imperfect predictors of outcome after mTBI.

Key words: CT-scan; head injury; mild traumatic brain injury; outcome; prediction

Introduction
MILD TRAUMATIC BRAIN INJURY (mTBI) is one of the most common neurological disorders, with an incidence of 100–300/100,000 population (Cassidy et al., 2004). To optimize treatment and for prognostic purposes, knowledge of the demographic, clinical, and radiological parameters related to adverse outcomes are relevant.

Computed tomography (CT) imaging of the brain is the gold standard to detect acute intracranial abnormalities related to head injury. In mTBI, CT is primarily used to identify life-threatening hematomas (extradural, subdural, and intraparenchymal), and other abnormalities including depressed skull fractures, that may require neurosurgical intervention, and further to decide if patients should be admitted, transferred to a neurosurgical center, or discharged (af Geijerstam and Britton, 2005; af Geijerstam et al., 2006; Ingebrigtsen et al., 2000; Smits et al., 2005; Stiell et al., 2001; Vos et al., 2002). The majority of mTBI patients show normal CT scan findings (af Geijerstam and Britton, 2003; Servadei et al., 2001). However, the incidence of CT abnormalities found after mTBI differs considerably among studies, ranging from 3.3–38.8%, depending on the inclusion and exclusion criteria used (Borczuk, 1995; Bordignon and Arruda, 2002; Culotta et al., 1996; Dunham et al., 1996; Gomez et al., 1996; Harad and Kerstein, 1992; Haydel et al., 2000; Hsiang et al., 1997; Ibanez et al., 2004; Iverson et al., 2000; Jeret et al., 1993; Livingston et al., 2000; Miller et al., 1996; Miller et al., 1997; Moran et al., 1994; Nagy et al., 1999; Sadowski-Cron et al., 2006; Shackford et al., 1992; Smits et al., 2005; Stein and Ross, 1990, 1992; Stiell

1Department of Neurology, 2Department of Neurosurgery, 3Department of Emergency Medicine, 4Department of Radiology, and 5Department of Epidemiology, Biostatistics and HTA, Radboud University Nijmegen Medical Centre (RUNMC), Nijmegen, the Netherlands.
dictive value of PTA, however, was not confirmed by others. This pre-
misson, predicted outcome as assessed with the Glasgow Coma
Scale (GCS), post-traumatic amnesia (PTA), initial complaints
and hypotension are strong predictors in moderate and severe
(headache, nausea, and dizziness), age, and gender for mTBI.

Variables are predictive of outcome for all TBI severities,
though the actual predictive value of the CT abnormalities is
variable. In this study we aim to gain insight into the composition
and frequency of several demographic, clinical, and CT char-
acteristics associated with patients suffering from mild (GCS
score 13–14), moderate (GCS score 9–12), or severe (GCS score
≤8) TBI (Perel et al., 2008). The GCS score, pupil reactivity,
major extracranial injury, age, and several CT characteristics
(compression of the basal cisterns and third ventricle, sub-
arachnoid hemorrhage [SAH], midline shift, and presence of a
non-evacuated hematoma) were the strongest independent
predictors of unfavorable outcome at 6 months post-injury.
However, it is not possible to use these factors in the modeling
of mTBI outcome prediction because no subdivision was
made by injury severity.

Only a few studies have compared the relative predictive
ability of CT characteristics with demographic and acute
clinical variables in a multivariate analysis (Hsiang et al.,
1997; Signorini et al., 1999; Stulemeijer et al., 2007; Wardlaw
et al., 2002). The presence of acute CT abnormalities was
associated with an increasingly worse 6-month outcome with
decreasing GCS score (Hsiang et al., 1997). In two studies,
both including more severely-injured TBI patients, the pres-
ence of a traumatic hematoma (Signorini et al., 1999), and a
combination of traumatic SAH and poor overall CT appear-
ance (Wardlaw et al., 2002) were independent predictors
when age, GCS score, and pupil reactivity were also entered
into the prediction models. In a recent study CT abnormalities
did not improve outcome prediction in mTBI when the
patient’s education, subacute post-traumatic symptoms
(nausea, vomiting, and pain), and concurrently sustained
extracranial injuries were included (Stulemeijer et al., 2007).

In this study we aim to gain insight into the composition
and frequency of several demographic, clinical, and CT vari-
ables of mTBI. To identify the predictors of functional out-
come after mTBI, we compared CT characteristics with dem-
ographic and clinical variables in a prospective cohort of
consecutive patients. After multivariate analysis, predictive
models were designed that may be useful in daily clinical
practice.

Methods

Subjects

All patients with mTBI aged 16 and older admitted to the
emergency department (ED) of the Radboud University Nij-
me gen Medical Centre (RUNMC), a level I trauma center with

et al., 2001, 2005; Styrke et al., 2007; Thriruppathy and Mu-
thukumar, 2004; Viola et al., 2000). In a selected group of
patients with clinical signs of skull (base) fractures the per-
centage of intracranial abnormalities found on head CT may
reach 70.2% (de Andrade et al., 2006). The value of CT in
identifying acute life-threatening hematomas in individual
patients has been clearly established. For this reason explo-
ration of the association between CT abnormalities and the
long-term effects of mTBI seems reasonable. However, the
search for CT predictors of long-term outcome after mTBI has
yielded conflicting results thus far. Both a positive correlation
(Hsiang et al., 1997; Kido et al., 1992; Perel et al., 2008; Sa-
dowski-Cron et al., 2006; Signorini et al., 1999; Smits et al.,
2008; van der Naalt et al., 1999a; Wallesch et al., 2001;
Wardlaw et al., 2002), and an absence of correlation
(McCullagh et al., 2001; Stulemeijer et al., 2007) between the
presence of intracranial abnormalities on CT and 6- to 12-
month outcome have been found. The primary outcome
measures in these studies differed considerably, and varied
dependent on death/survival to cognitive functioning and the
presence of post-traumatic complaints. Furthermore, the CT
characteristics that have surfaced as predictors of adverse
outcome differ per study. Traumatic subarachnoid hemor-
rhage (Wardlaw et al., 2002), edema (van der Naalt et al.,
1999a), the presence of focal lesions (van der Naalt et al.,
1999a; Wallesch et al., 2001), visible hematomas (Signorini
et al., 1999), signs of diffuse axonal injury, signs of paren-
chymal damage (Smits et al., 2008), and the size of focal
lesions (Kido et al., 1992), have been identified as outcome
predictors. Finally, the mere presence of acute CT abnormal-
ities (Hsiang et al., 1997; Sadowski-Cron et al., 2006), and the
overall CT appearance (Wardlaw et al., 2002), have also been
suggested to be associated with functional outcome. Unfortu-
ately, it is difficult to draw solid conclusions from these
studies of the predictive value of CT for mTBI outcomes,
because CT predictors were not compared with clinical and
demographic factors (Smits et al., 2008; van der Naalt et al.,
1999a), the studies used relatively small sample sizes (Kido
et al., 1992; van der Naalt et al., 1999a; Wallesch et al., 2001),
or data were only analyzed in a univariate way (McCullagh
et al., 2001; Sadowski-Cron et al., 2006; Wallesch et al., 2001).
In addition, mTBI patients were combined with more severely
brain-injured patients (Kido et al., 1992; Signorini et al., 1999;
van der Naalt et al., 1999a; Wallesch et al., 2001; Wardlaw
et al., 2002). This may mistakenly result in concluding that CT
variables are predictive of outcome for all TBI severities,
though the actual predictive value of the CT abnormalities is
based on their predictive power in the most severely affected
patients.

In contrast, studies investigating clinical and demographic
predictors of outcome, but excluding radiological character-
istics, emphasize the predictive ability of the Glasgow Coma
Scale (GCS), post-traumatic amnesia (PTA), initial complaints
(headache, nausea, and dizziness), age, and gender for mTBI
(Carroll et al., 2004; van der Naalt, 2001). Whereas hypoxia
and hypotension are strong predictors in moderate and severe
TBI (Hukkelhoven et al., 2005), they have not emerged as
outcome predictors in mTBI (Carroll et al., 2004). In a multiple
regression analysis PTA, but not GCS score at hospital ad-
mission, predicted outcome as assessed with the Glasgow
Outcome Scale (GOS) (van der Naalt et al., 1999b). This pre-
dictive value of PTA, however, was not confirmed by others
(McCullagh et al., 2001; Ponsford et al., 2000). Additional
extracranial injuries such as long bone or pelvic fractures may
prolong the rehabilitation period and are independent out-
come predictors in mTBI (Signorini et al., 1999; Stulemeijer
et al., 2006, 2007). Furthermore, it has been consistently shown
that acute post-traumatic complaints (e.g., dizziness, head-
ache, or vomiting) in the ED predict post-traumatic com-
plaints at 1–6 months post-injury (Chamelian and Feinstein,
2004; de Kruijk et al., 2002; Savola and Hillbom, 2003; Stule-
meijer et al., 2007). Interestingly, GCS score had only a very
modest predictive capacity in a number of studies (McCul-
lagh et al., 2001; Stulemeijer et al., 2007; van der Naalt et al.,
1999b). Finally, using multivariate analysis, results of a large
prospective study demonstrated the predictive value of age,
pre-existing physical limitations, and a history of brain illness
(Thorhill et al., 2000); however, the variance in outcomes in
this study was low.

A recent large international multicenter study investigated
the predictive value of demographic, clinical, and CT char-
acteristics multivariately in patients suffering from mild (GCS
score 13–14), moderate (GCS score 9–12), or severe (GCS score
≤8) TBI (Perel et al., 2008). The GCS score, pupil reactivity,
major extracranial injury, age, and several CT characteristics
(compression of the basal cisterns and third ventricle, sub-
arachnoid hemorrhage [SAH], midline shift, and presence of a
non-evacuated hematoma) were the strongest independent
predictors of unfavorable outcome at 6 months post-injury.
However, it is not possible to use these factors in the modeling
of mTBI outcome prediction because no subdivision was
made by injury severity.
a referral area of 2.5 million inhabitants, between January 1998 and January 2006, were eligible for inclusion. mTBI was defined as an acute insult to the brain caused by an external physical force, and an ED GCS score of 13–15 after initial resuscitation, or a GCS score of 13–15 at admission before sedation and intubation during resuscitation for a nonelective cause. Patients suffering from penetrating head injury, defined as head injury caused by penetration of a foreign body like a knife or bullet, were excluded. Polytrauma patients with significant extracranial injury (Injury Severity Score [ISS] ≥16) were not excluded.

The data for this study were obtained from the Radboud University Brain Injury Cohort Study (RUBICS). RUBICS is an ongoing prospective observational cohort study that started January 1, 1998. All consecutive patients, including children, admitted to the ED of the RUNMC with a diagnosis of mild, moderate, or severe TBI are included. Patients are registered in the RUBICS database when according to the hospital protocol, a neurologist and/or neurosurgeon is consulted in the ED when a head trauma patient is presented with: (1) a GCS score of 3–14; or (2) a GCS score of 15 with loss of consciousness (LOC) and/or PTA; or (3) a GCS score of 15 without LOC or PTA, but fulfilling additional criteria according to the guidelines proposed by the European Federation of Neurological Societies (EFNS), which include unclear or ambiguous accident history; persistent or progressive headache, nausea, and vomiting; intoxication with alcohol or drugs; epileptic seizure; coagulation disorders; use of platelet aggregation inhibitors or oral anticoagulation; confusion, retrograde amnesia, or focal neurological deficits; age ≥60 and <2 years; high-energy accident; or visible trauma above the clavicles (including signs of skull or skullbase fracture) (Vos et al., 2002). Recently it was shown that the EFNS guidelines have 100% sensitivity for the identification of neurocranial complications after minor head injury (Smits et al., 2007a). Using these guidelines all mTBI patients would be included in the RUBICS database, which is also in accordance with the criteria of the mTBI Committee of the Head Injury Interdisciplinary Special Interest Group of the American Congress of Rehabilitation Medicine (Kay et al., 1993).

The RUBICS database comprises demographic data (age and gender), clinical and radiological injury variables, and outcome scores. Injury characteristics recorded for this study include: injury type, presence of hypotension (systolic BP <90 mm Hg, equal to shock class III–IV [American College of Surgeons, 2004]), and hypoxia (oxygen saturation <90% as measured by pulse oximetry), during the prehospital period or at the ED. Further, the Abbreviated Injury Scale of the Head (AISH) score, ISS score (Baker et al., 1974), GCS score, pupil responses, presence and duration of coma, and PTA were also recorded. The presence and duration of both LOC and PTA were based on witness and paramedic reports when available. In the ED, the presence of amnesia and ongoing PTA were determined by emergency physicians and neurological consultants using a PTA questionnaire. When information regarding the prehospital presence of LOC and PTA was ambiguous this was recorded as such, but for statistical analysis these cases were added to the “absent” category. Finally, we recorded a clinical suspicion of day-of-injury alcohol intoxication or definite day-of-injury intoxication when the blood alcohol level exceeded ≥100 mg/L, and the use of oral anticoagulants. Additionally, several CT characteristics and the Trauma Coma Databank (TCDB) CT classification were recorded (Marshall et al., 1991). To quantify additional extracranial injuries, an alternative modified ISS score was calculated based on the three most severely injured body areas excluding the head, as the ISS-extracranial score (ISSe).

Patients were categorized as having isolated mTBI (versus polytrauma) when they sustained a mild TBI without any substantial additional injury, defined by an AIS score <2 in one of the AIS-ISS body regions. Patients were assessed by neurologists (residents) and/or neurosurgeons (residents) according to hospital protocol, and data were recorded as such, after which all clinical data were collected by a trained research nurse as soon as possible post-injury, generally on the day of injury, and recorded on forms before entry into our digital database.

**Outcome assessment**

Outcome was assessed at 6 months post-injury according to the Glasgow Outcome Score-Extended (GOSE), using a structured interview during regular visits to the outpatient clinic or during consultation by telephone (Wilson et al., 1998). In short, the GOSE is an 8-point scale expressing functional outcome, ranging from 1 = death, to 8 = complete recovery. GOSE score 2 represents a vegetative state, GOSE score 3 indicates 24-h dependency (at home), GOSE score 4 means the patient is dependent but can do without help for at least eight consecutive hours, GOSE score 5 denotes independence in activities of daily living but no resumption of former employment, GOSE score 6 means reduced capacity for work, and GOSE score 7 indicates resumption of former employment, but with persistent complaints that interfere with activities of daily living (Wilson et al., 1998). A GOSE score of 6 or lower was considered as an unfavorable outcome in this study and was dichotomized as such for statistical purposes. Patients not visiting the outpatient clinic were sent a GOSE questionnaire by regular mail, and if not returned a reminder was sent (Wilson et al., 2002). Finally, we attempted to reach all non-responding patients by telephone. If no outcome was obtained directly from the patient, charts and correspondence were reviewed to determine outcome and construct a GOSE score using the structured interview (Wilson et al., 1998) as a guideline. Because retrospective determination of outcome based on chart review rather than a formal personal interview may be considered artificial and susceptible to errors, several analyses were also carried out without inclusion of these patients. Outcomes determined within 3 months were also accepted if no outcome at 6 months was available. When the patient had a GOSE score of 7 or 8 by 4.5 months post-injury, it was considered a definitive outcome. Patients with no outcome score or an outcome score that did not meet the above criteria were considered lost to follow-up.

**Computed tomography**

Patients were scheduled to undergo a CT scan of the head according to EFNS guidelines (Vos et al., 2002). Only the initial CT scans of patients admitted to the hospital within 72 h after sustaining head injury were used in this study. Each CT scan was scored as soon as possible post-injury by one of three raters (B.J., T.B. and P.E.V.) using a predefined format (see below). In addition, all scans were classified according to the...
Using a structured format the following CT characteristics were recorded on data entry sheets:

- The status (presence, compression, or absence) of the ventricular system and the cisterns
- The presence, location, type, number, and size of any low-, mixed-, or high-density lesions, including subdural hematomas (SDH), epidural hematomas (EDH), intraparenchymal hematomas, and hemorrhagic contusions; intraparenchymal hematomas and hemorrhagic contusions were combined into one category, hemorrhagic contusions; where applicable the volume of space-occupying lesions was calculated as previously described (Pasqualin et al., 1991; Vos et al., 2001)
- The presence and type of subarachnoid and intraventricular hemorrhage
- The presence and location (subcortical, basal ganglia/corpus callosum, or brainstem) of punctate hemorrhages (diameter ≤5 mm)
- The presence and location of edema (focal or diffuse)
- The presence and quantity of midline shift
- The presence of pneumocephalus
- The presence and type of facial, vault, or skullbase fractures
- The presence of extracranial hematomas

**Statistical analysis**

To detect significant differences between the patients included in the outcome analysis and the patients lost to follow-up, the Student’s t-test, chi-square test, and non-parametric variants were used where applicable. We used binary logistic regression analysis to identify the demographic, clinical, and CT characteristics associated with unfavorable outcome after mTBI. Missing data were excluded from the analysis. As dependent variables we dichotomized the 6-month outcome as favorable (GOSE score 7 or 8), or unfavorable (GOSE score 1–6). Initially all demographic, clinical, and CT characteristics, were tested univariately. Age was analyzed per year, and GCS, AISH, ISS, and ISSe scores were all analyzed numerically. The other clinical variables were binary (presence versus absence). With regard to the CT parameters, midline shift was analyzed per millimeter, the volume of the lesions per milliliter, and the number of hematomas/contusions was assessed. The remaining variables were nominal: ‘largest lesion,’ ordinal: ‘presence of lesions,’ or dichotomous categorical variables. The clinical variables were analyzed for the entire mTBI group, and CT characteristics were analyzed only in patients in whom a CT of the head was performed.

Possible predictors of unfavorable outcome at 6 months post-mTBI were analyzed multivariately, using the forward stepwise likelihood ratio method. The clinical and demographic variables were combined, as were the CT variables. Besides a multivariate analysis including the ISS, a combination of AISH and ISSe replacing the ISS was included as an analogue multivariate analysis. In addition, by using the independent predictive variables, three prediction rules were subsequently used to design the third "combination" rule. The three prediction models were analyzed for their sensitivity and specificity in predicting unfavorable outcome using receiver operating characteristic (ROC) analysis, quantified by the area under the receiver operating curve (AUC). This is a measure of predictive discrimination, in which a score of 0.50 (50%) is equivalent to random guessing, and a score of 1.00 (100%) is perfect prediction. The higher the AUC, the higher the sensitivity and specificity (i.e., the ability to correctly predict outcome).

Previously we demonstrated a strong relationship between extracranial injuries and outcome after mTBI (Stulemeijer et al., 2006). Therefore, we also explored the predictive value of all variables in isolated mTBI using the same procedures as those described above.

Throughout we used a two-sided p value of 0.01 as the criterion for significance, except for the AUC (for which we used p < 0.05). We chose 0.01 in order to avoid irrelevant findings of statistical significance due to the large number of variables involved.

**Results**

Figure 1 shows the inclusion and exclusion criteria and the total numbers of patients considered for the study. The demographic and clinical characteristics at presentation were evaluated in 2784 patients, the CT characteristics were evaluated in 1999 patients, and for the outcome prediction 1069 patients were analyzed. In 53 (5.0%) of these patients the GOSE scores were determined based on outcome information from the patients’ charts.

**FIG. 1.** Diagram showing the inclusion and exclusion criteria of the patients in this study (RUBICS, Radboud University Nijmegen Brain Injury Cohort Study; TBI, traumatic brain injury; ED, emergency department; CT, computed tomography).

4188 TBIs included in the RUBICS database (1998–2005)

Excluded
675 age < 16 years
12 penetrating TBI
126 moderate TBI
574 severe TBI
17 ED/CT > 72h

2784 Mild TBI

765 no head CT
1999 head CT

930 lost to follow-up
- From abroad (n = 25)
- Non-responders (n = 905)

1069 included in outcome analysis
Demographic and clinical characteristics of all included patients, and the patients eventually used in the outcome analysis, are shown in Table 1.

We focused our analysis on the patients that underwent a head CT. In this group demographic and clinical data were missing in less than 1.5%, except for the presence of alcohol intoxication (3%; \( n = 61 \)). The presence of PTA was uncertain in 261 patients (9.4%), and LOC in 694 (24.9%) patients. Our study participants were predominantly male (68%) with a mean age of 42.7 years. The leading causes of trauma were traffic accidents (55%) and falls (30%). The majority of patients experienced mild trauma, as represented by the low mean ISS (9.1). In 19 (0.7%) patients neurosurgical intervention was necessary. Seven patients were operated on for EDH (one in combination with a compression fracture), and two patients for a combination of an EDH and a SDH. A total of 38 (2%) patients died, and 257 (13%) mTBI patients had an unfavorable outcome (GOSE score 1–6). Although the differences were small, the patients included in the outcome prediction analyses differed significantly from the patients lost to follow-up, with regard to gender, trauma mechanism, GCS at the ED, AISH score, ISS score, day-of-injury alcohol intoxication, presence of PTA (for duration of PTA they did not differ significantly), and neurological intervention. Thus they had a more severe injury profile. The distribution of major CT characteristics, including the patient distribution over the different categories of the TCDB CT classification, is presented in Table 2.

For all CT characteristics fewer than 0.5% of the required values were missing. Intracranial abnormalities were found in 389 (19.5%) patients. When vault and skullbase fractures were included, abnormalities were present in 414 (20.7%) patients. Edema was the most frequent intracranial abnormality (239; 12%), with an inter-rater agreement (B.J. and P.E.V.) of 82%. Isolated edema, focal or diffuse, without any other intracranial abnormality was seen in 63 (3%) patients. In 186 patients (9%) one or more lesions, excluding punctate hemorrhages, were present; in 40 patients (2%) an EDH was the dominant lesion, in 50 patients (3%) an SDH was the dominant lesion, and in 95 patients (5%) a hemorrhagic contusion was the dominant lesion. Of all lesions, 40 had a volume of 25 mL or more. The mean volume of the largest lesion per patient was 21.0 mL (median: 6.8 mL). Traumatic SAH was demonstrated in 115 patients (6%), and 67 patients (3%) showed evidence of abnormal basal cisterns. Finally, in 52 patients (3%) there was a midline shift (mean 4.6 mm; median 3.9 mm). Subdivided by GCS score, intracranial abnormalities were found in 16% of patients with a GCS score of 15, 27% of patients with a GCS

(continued)
score of 14, and 46% of patients with a GCS score of 13. Aside from the status of the foramen magnum and basal cisterns, the patients lost to follow-up were significantly less severely injured according to CT abnormalities, than patients for whom GOSE scores were available.

Univariate binary logistic regression analysis showed that several clinical and CT characteristics predict outcome after mTBI (Table 3). In addition we re-analyzed the predictive value of the presence of PTA and LOC, including the ambiguous scores; again the presence of PTA (odds ratio [OR] 1.0, 99% confidence interval [CI] 0.7, 1.5) and LOC (OR 0.8, 99% CI 0.5, 1.2) were not indicative of outcome. When the univariate analysis was performed without the neurosurgical patients, the GCS (OR 0.8, 95% CI 0.6, 1.02), and the presence of pneumocephalus (OR 2.0, 95% CI 0.9, 4.4) lost their predictive value. Multivariate analysis of the demographic and clinical variables showed that age, ISSe, and AISH scores were predictors of unfavorable outcome, whereas day-of-injury alcohol intoxication was associated with a favorable outcome. The multivariate analysis was carried out without the neurosurgical patients as well, which did not change the results. A multivariate analysis of the possible clinical predictors and age done without the 53 patients that had an interpreted GOSE score did not change the results; only the 99% CIs changed minimally (data not shown). These four variables were used to design the “clinical” predictive rule (Table 5). The combination of ISSe and AISH could be replaced by the total ISS score (OR 1.07, 99% CI 1.06, 1.1). Multivariate analysis of the CT characteristics showed that the number of hemorrhagic contusions and the presence of facial fractures were outcome predictors (Table 3). From these characteristics the predictive “CT rule” was formulated (Table 5). The multivariate analysis of potential CT predictors was carried out sequentially, excluding the neurosurgical patients and the 53 patients mentioned above as well. Again the results did not change significantly; the OR of the number of hemorrhagic contusions slightly increased to 1.9 (99% CI 1.2, 3.1), as was true for the OR of the presence of facial fractures (OR 1.8, 99% CI 1.2, 3.0).

Thus age, ISSe, alcohol intoxication, and the number of hemorrhagic contusions emerged as significant outcome predictors after multivariate analysis of the combined demographic, clinical, and CT variables (Table 4). The third predictive rule, “combined,” was designed using these predictors (Table 5C). When we reanalyzed the multivariable analysis without, successively, the neurosurgical and the interpreted GOSE, the OR of the number of hemorrhagic contusions increased from 1.9 to 2.1 (95% CI 1.2, 3.5).

Of the patients with a head CT, 1315 (66%) suffered from an isolated mTBI. Of these patients, 223 (17.0%) had intracranial abnormalities. Abnormal CTs were found in 165 (24.4%) patients in the polytrauma group. For outcome prediction 669 (51%) isolated mTBI patients could be analyzed. Unfavorable outcomes occurred in 128 (16%) patients with isolated mTBI, in contrast to the 152 (36%) patients in the polytrauma group. Death occurred in 26 (3%) of patients with isolated mTBI, and in 14 (3%) polytrauma patients.

In the isolated mTBI group univariate (n = 669; results not shown), and subsequent multivariate analysis of the demographic and clinical variables showed that age (OR 1.02; 99% CI 1.003, 1.03), AISH score (OR 1.5, 99% CI 1.2, 2.0), and day-of-injury alcohol intoxication (OR 0.3, 99% CI 0.2, 0.7) were predictors of outcome. When the CT parameters were analyzed, only the number of hemorrhagic contusions demonstrated independent predictive value (OR 2.4, 99% CI 1.3,4.4). After multivariate analysis of the demographic, clinical, and CT variables, age (OR 1.02, 99% CI 1.004, 1.03), AISH score (OR 1.5, 99% CI 1.1,2.0), and alcohol intoxication (OR 0.3, 99% CI 0.2,0.7) proved to be outcome predictors. In this analysis, AISH was not replaced by the number of hemorrhagic contusions, in contrast to the analysis of the complete mTBI group. In conformity with the models predicting outcome in the entire mTBI group, in the isolated mTBI group, again three predictive rules were designed (Table 6).

The results of the ROC analysis showed that the predictive value of both CT models was limited, with AUCs of 0.57 and 0.56 (Fig. 2 and Table 7). The “clinical” models demonstrated the highest predictive values. Combination of clinical and CT predictors, so-called combination models, did not improve the performance of the “clinical” models. In the mTBI group the rule based on clinical variables had a higher AUC than the rule based on the combination of clinical and CT parameters. This seems to contradict the rule that states that a wider choice of variables always leads to an improved model. However, it
is a result of missing values and of the variable selection procedure, which dictated that only significant variables could be used. We therefore reran the model with less strict criteria and found that, although the AUCs increased slightly, the AUC of the model including clinical and CT characteristics never showed any significant improvement over the model using clinical variables only.

The 10% of the mTBI patients with the lowest scores (young, alcohol-intoxicated patients without extracranial injuries and no intraparenchymal contusions), when assessed with the "combination" model had a probability of an unfavorable outcome of 7.8%. On the other hand, in the mTBI patients with the highest scores (elderly patients with extracranial injuries and intraparenchymal contusions, without

alcohol intoxication), or the lowest 10%, the probability of an unfavorable outcome was 49.5%.

Discussion

The main finding of this prospective cohort study is that of all demographic and acute injury characteristics studied, age, extracranial injury (as represented by the ISS or ISSe), and day-of-injury alcohol intoxication were the strongest independent predictors of functional outcome at 6 months after mTBI. The only CT characteristic that added marginally to the prediction of outcome was the number of intraparenchymal hemorrhagic contusions.

Our finding of the predictive value of age and additional extracranial injuries are in accord with other results seen in the literature (Perel et al., 2008; Signorini et al., 1999; Stulemeijer et al., 2006, 2007; Thornhill et al., 2000). Of the clinical variables, PTA (present in 61% of patients), and LOC (present in 41% of patients) did not show predictive value after univariate analysis. The percentage of our patients with LOC and/or PTA appears to be lower than that found in the literature, where LOC was present in 47.2–64.4% (Borczuk, 1995; Smits et al., 2005; Stiell et al., 2005), and PTA was present in 69.2–73.7% (Savola and Hillbom, 2003) of mTBI patients. One explanation for this discrepancy may be that we categorized patients in whom the presence of PTA and LOC was unclear (9% for PTA and 25% for LOC) as not experiencing these sequelae. However, in the logistic regression analysis we analyzed the ambiguous PTA and LOC scores both included in and excluded from the “present” group, and found no significant difference. Further, we deliberately included patients without PTA and LOC, since the absence of these factors in head-injured patients does not fully rule out mTBI (Smits et al., 2007b; Viola et al., 2000).

The presence of day-of-injury alcohol intoxication was associated with favorable outcomes in our study. One explanation may be that alcohol intoxication can interfere with the initial assessment of injury severity, because it potentially affects the level of consciousness and post-acute cognitive and memory functioning (Jurkovich et al., 1992; Kelly et al., 1997; Tate et al., 1999). Hence the attending physician may overestimate the effects of head injury in intoxicated patients, for instance due to a suboptimal GCS score (13–14), or the apparent presence of PTA as a result of diminished attention, and diagnose a mTBI when in fact the patient did not suffer any brain injury. Recent studies have shown no significant difference in short-term and long-term neuropsychological functioning between mTBI patients with and those without day-of-injury alcohol intoxication (Lange et al., 2008; Wilde et al., 2004). Nevertheless, alcohol intoxication should never lead to an underestimation of trauma severity. In intoxicated patients it may be necessary to exclude life-threatening intracranial injury first, before designating alcohol or drug use as the cause of impaired consciousness, amnesia, or behavioral disturbances (National Institute for Clinical Excellence, 2003).

The frequency of CT abnormalities in mTBI patients with hospital admission GCS scores of 13–15 seen in our study (19.5% intracranial abnormalities, and 20.7% when skull or skullbase fractures are included) is higher than that found in several other studies: 6% (Ibanez et al., 2004), 7.5% (Styrke et al., 2007), 9.8% (Smits et al., 2005), 12% (Stiell et al., 2001), and 12.1% (Stiell et al., 2005). There are, however, studies that support our data, showing comparable or even higher frequencies of CT abnormalities: 16.9% (Shackford et al., 1992), 17.2% (Stein and Ross, 1992), and 25.9% (Bordignon and Arruda, 2002). A potential reason for these discrepancies concerns the inclusion criteria of the mTBI patients. Most studies included only patients with LOC and/or PTA. Head injury without LOC and PTA, however, does not preclude the presence of intracranial abnormalities, and they may be present in 0.5–4.9% of patients (Smits et al., 2007b; Viola et al., 2000). In our study head-injured patients without LOC and PTA were included, because our hospital protocol is based on the presence of risk factors rather than loss of or impairment of consciousness, which are part of the EFNS guidelines (Vos et al., 2002). These guidelines are derived in part from the Canadian (Stiell et al., 2001) and New Orleans (Haydel et al., 2000) CT prediction rules, and therefore lead to a higher frequency of CT abnormalities. Moreover, a recent study showed that when the EFNS head-CT guideline is directly compared to other protocols, the EFNS protocol has the

Age in years, AISH score in points, and ethanol intoxication (1 present, 0 absent) are used. To calculate the probability of an unfavorable outcome the value of A, B, or C has to be inserted into the formula: \( 1/(1 + e^{-A, B, or C}) \).

mTBI, mild traumatic brain injury; AISH, Abbreviated Injury Scale Head score; CT, Computed tomography, hem., hemorrhagic.
highest sensitivity in detecting intracranial abnormalities in mTBI (Smits et al., 2007a). Further, we included secondary referrals from level II and III centers, who by definition have intracranial abnormalities, and polytrauma patients with mTBI, who are more prone to having intracranial lesions than isolated head-injured patients.

In our study, several individual CT characteristics, such as the status of the basal cisterns, and the presence of SAH, edema, and pneumocephalus were associated with worse outcome after mTBI. However, after multivariate logistic regression analysis, we found only two independent CT predictors of outcome (the presence of facial fractures and the number of intracranial hemorrhagic contusions). The negative influence of facial fractures on post-traumatic neuropsychological and functional outcome after mTBI has been previously demonstrated (Bisson et al., 1997; Martin et al., 2002). The presence and size of hemorrhagic contusions, including traumatic intraparenchymal hemorrhages, have an adverse effect on outcome after TBI, particularly in severe TBI (Maas et al., 2007). The negative effect of hemorrhagic contusions on outcome has also been demonstrated in studies that incorporated more severely injured TBI patients (van der Naalt et al., 1999a; Wallesch et al., 2001). In contrast to severe TBI, in mTBI the size of intracranial lesions has no influence on outcome (Marshall et al., 1991).

From the independent predictors we composed three simple prediction models. The first model consisted of demographic and clinical variables, the second model of CT parameters, and the third model of combined clinical/demographic and CT characteristics. Whereas an AUC of 0.50 equals random guessing, and an AUC of 1.0 is the best possible score, the CT model in the overall mTBI group had only limited predictive value (AUC 0.57), compared to the moderate AUC of 0.71 of the clinical model. Moreover, the CT characteristics did not add any predictive value, resulting in an AUC of 0.69 in the combined model. In isolated mTBI the AUC of the CT model (AUC 0.56; 95% CI 0.50, 0.62) did not reach statistical significance, and the AUC of the clinical model was only moderate, at 0.69. Of course CT remains an indispensable tool to identify patients in need of neurosurgical intervention. The presence of CT abnormalities might further delay recovery and influence short-term outcome, but the value of CT appears to be limited for the prediction of long-term outcome in mTBI patients.

The importance of these findings is that contrary to intuitive beliefs, and unlike those with moderate to severe TBI, CT, demographic, and clinical characteristics are only modest predictors of outcome after mTBI. One reason for these findings may be that for prediction of outcome post-mTBI, factors other than age, clinical, and CT characteristics should be considered. Pre-existing physical comorbidities, severe post-concussional symptoms, and post-traumatic stress immediately after mTBI appear to affect the number or patients with post-concussional symptoms 6 months or more after mTBI (Stu-
lemelte et al., 2007). Further, the number of years of formal education, the presence of nausea or vomiting on ED admission, concurrently sustained extracranial injuries, and the pain levels seen early after injury, all appear to affect time to return to work after mTBI (Stulemeijer et al., 2007). A survey of U.S. Army infantry soldiers done after their return from Iraq demonstrated that post-traumatic stress disorder and depression are mediators of the relationship between mTBI and physical health problems more than 3 months post-injury (Hoge et al., 2008). None of these factors, apart from additional extracranial injury, were included in the current study. We also did not investigate the roles of other potential predictors of outcome, including genetic polymorphisms and biomarkers of brain damage. Future predictive models might have stronger predictive power if these variables were added.

Limitations

This study has some limitations. First, only mTBI patients requiring neurological or neurosurgical consultation at the ED were included. Therefore patients seen only by the ED physician were not included, which may have caused inclusion bias. According to our hospital protocol, patients experiencing head injury without LOC or PTA, a GCS score of 15 or more, and no risk factors (i.e., not fulfilling the EFNS criteria described above) (Vos et al., 2002), were not included. This category of patients, with slight head injury without mTBI, has an extremely low risk of having intracranial abnormalities, and thus they would contribute little to our predictive model. Moreover, these patients were excluded from most of the studies cited above, and they do not fulfill the criteria for mTBI as defined by the mTBI Committee of the Head Injury Interdisciplinary Special Interest Group of the American Congress of Rehabilitation Medicine (Kay et al., 1993).

Additionally, patient follow-up was of concern despite the prospective design of the study. In the CT-only group 46% patients were lost to follow-up, making extrapolation to our entire population more difficult. The low follow-up rate was partly caused by high rates of patients with alcohol and drug abuse problems, psychiatric patients, and homeless persons. A number of foreigners, who were visiting and thus unavailable for follow-up consultations, was also included. Furthermore, we suspect that mTBI patients with few complaints or symptoms are unlikely to visit the outpatient clinic. The high rate of loss to follow-up and the bias that may result has been described previously by others (Corrigan et al., 2003). Generalizability may also be limited by the fact that the patients included in the outcome analysis had a more severe injury profile, as demonstrated by GCS, AISH, and ISS scores, and CT characteristics. Our models may therefore have the most value for more severely injured mTBI patients, especially those that undergo a head CT scan. For less severely injured mTBI patients, a different type of prognostic model may yield better results.

Third, although the patients were prospectively selected and included in the RUBICS database, the clinical data were collected from the patient charts by a research nurse, and many of the CT scans were reviewed within 24 h post-injury. This may have given our study a partly retrospective nature, and may have led to missing data. The additional follow-up was nonetheless prospectively performed. A small proportion of the GOSE scores (n = 53, 5.0%) were derived from patient charts using accessory queries that were previously formulated (Wilson et al., 1998). When these questions could not be answered adequately using the available data, the patient was regarded as lost to follow-up. We therefore think it unlikely that invalid GOSE scores were used in this study. Nevertheless, we reran the various multivariate analyses without these 53 patients, and only minimal changes in the ORs and CIs were found. Thus we based the final prediction models on the results from the multivariate analyses performed on all 1069 patients.

Finally, no external validation has been performed. The prediction models should be validated by a separate cohort study to determine its generalizability.

Conclusion and future research

Our study shows that age and extracranial injuries (high ISSe scores) are the strongest predictors of unfavorable outcome in mTBI, and they are stronger than admission CT characteristics. Further, the presence of day-of-injury alcohol intoxication is associated with favorable outcomes after mTBI, probably due to its interference with the initial assessment of injury severity. We propose a simple prediction model using these factors, and we believe that future prognostic models for mTBI should include these variables. To ensure its applicability, the validity of this prediction model is essential, and thus an external validation study is necessary.
