Key Words
Morbid obesity · Bariatric surgery · Mental health · Quality of life · Conversion

Summary
Background: A low quality of life has been regarded a cue to action. Some patients with unsuccessful weight loss after laparoscopic adjustable gastric banding (LAGB) undergo a conversion of gastric banding to gastric bypass. This study examines whether patients who did or did not undergo conversion to gastric bypass differed in quality of life before and after gastric banding. Methods: Of 34 patients with unsuccessful weight loss after gastric banding (excess body mass index loss < 25%), 14 had a conversion to gastric bypass 2 years or more after gastric banding. All patients completed the RAND-36 quality of life questionnaire before gastric banding. After gastric banding, 24 patients (70.6%) filled out the RAND-36 at 6, 12, and 24 months. Results: Pre-banding and post-banding mental quality of life was lower in the conversion compared to the non-conversion group. Conclusion: Our results suggest that a relatively stable lower mental quality of life is a signal for further intervention. The bariatric team and patients should be aware that mental health may play a role in the decision for conversion to gastric bypass. The possible mechanisms underlying this finding, and limitations of the study are discussed.

Introduction
Laparoscopic adjustable gastric banding (LAGB) is a widely used restrictive bariatric operation [1]. Due to its reversibility and adjustability, it is considered to be the least invasive bariatric procedure [2]. However, the weight loss resulting from gastric banding is less compared to a combined restrictive and malabsorptive procedure like gastric bypass [3]. Some patients with insufficient weight loss after gastric banding undergo conversion to gastric bypass, which often results in superior weight loss [4–6].

Clarification of the factors that affect the decision of patients and surgeons to convert to gastric bypass when gastric banding has led to unsuccessful weight loss will help the discussion about the appropriateness of these factors. To date, no studies have addressed this question. Health psychology theories emphasize that perceived consequences of obesity determine health behaviors [7, 8]. A low quality of life is considered a ‘cue to action’, i.e. a signal that a change of health status is needed. In line with this idea, lower levels of quality of life have been associated with treatment-seeking behavior in obesity [9]. Severely obese persons seeking surgical obesity treatment demonstrated on average the worst quality of life compared to other overweight and obese populations; even after adjustment for weight [10].

The aim of the present study was to examine whether patients who did or did not undergo conversion to gastric bypass differed in pre-conversion quality of life. Quality of life was assessed before gastric banding and several times after gastric banding, but before conversion. We hypothesized that ‘unsuccessful’ patients who have a conversion operation are the ones with a lower pre-conversion quality of life.
Material and Methods

Patients and Procedures

Between November 2000 and April 2004, 156 patients were subjected to a LAGB procedure at the St. Antonius Hospital Nieuwegein, the Netherlands, using the Lap-Band® system (INAMED Health, Santa Barbara, CA, USA), following screening by a bariatric surgeon, an endocrinologist, a psychologist, and a dietician. Surgical indications were a BMI ≥ 40 or a BMI between 35 and 40 with serious co-morbidity. The operation was performed according to the techniques described by Belachew et al. [11]. Weight observations after surgery were recorded in the hospital. Weight outcome was defined as percent of excess body mass index loss (%EBL) according to standard procedures [12]. We selected patients with unsuccessful weight outcome 2 years or more after LAGB (defined as %EBL < 25\%) out of a group of 113 patients who participated in a survey study which has received the necessary ethical approval [13]. We used the last weight observation after LAGB and if applicable before conversion to gastric bypass that was recorded. Thirty-four of the 113 patients (30\%) had an unsuccessful weight outcome (%EBL < 25\%). Of these ‘unsuccessful’ patients, 14 underwent conversion to gastric bypass. There were no differences in the %EBL between the conversion group (mean (M) = 11.7; standard deviation (SD) = 10.9) and non-conversion group (M = 12.5; SD = 13.5), t(32) = 0.2, p = 0.85. Because for the conversion group, the post-banding weight evaluation ended when the bypass operation was performed, the post-operative follow-up interval recorded in months of the last weight observation was longer for the non-conversion group (M = 57.9; SD = 17.4) compared to the conversion group (M = 45.0; SD = 14.8), t(32) = 2.2, p = 0.03. The conversion operation was conducted on average 48 months (SD = 15.6; range = 23.7–77.9) after gastric banding. The groups did not differ in demographic characteristics, as shown in Table 1. All patients completed the quality of life measure before gastric banding. After gastric banding, 24 patients (70.6\%) filled out the quality of life measure at 6, 12, and 24 months post-banding, and 10 of these 24 patients were in the conversion group. There were no differences between the patients who did or did not complete all post-operative quality of life measures on demographic characteristics, BMI, or pre-banding quality of life as compared to age and gender-specific norms. We also used the scores of the 8 subscales of the RAND-36 to calculate 2 summary scores by a standard equation: Physical Component Summary (PCS or physical health) and Mental Component Summary (MCS or mental health) [15].

Quality of Life Measurements

To measure quality of life, the RAND-36 was used [14]. Quality of life scores of the separate subscales were expressed as mean deviations from a general Dutch norm population [14]. The lower scores reflect poorer health as compared to age and gender-specific norms. We also used the scores of the 8 subscales of the RAND-36 to calculate 2 summary scores by a standard equation: Physical Component Summary (PCS or physical health) and Mental Component Summary (MCS or mental health) [15].

Statistical Analysis

Though the sample sizes were rather small, the score distributions of all quality of life dimensions were sufficiently normal to allow parametric statistics [16]. The quality of life before gastric banding of the conversion and non-conversion groups were examined with independent sample t-tests for all 34 patients. In 24 patients, repeated measures analyses of variance were used on pre-banding and 6, 12 and 24 post-banding quality of life with group (conversion versus non-conversion) as between-subject factor. For the subscale ‘emotional role limitations’, the analyses were run on 23 patients, as from 1 patient information was missing. Effects sizes (Cohen’s d) were computed. Effect sizes between 0.2 and 0.5 reflect a small effect, between 0.5 and 0.8 a medium effect, and above 0.8 a large effect [17]. Analyses were performed with SPSS 15.0 (SPSS Inc., Chicago, IL, USA); p values of less than 0.05 were considered to be significant.

Results

Table 2 shows the pre-banding quality of life for the conversion and non-conversion groups. Patients with and without conversion did not differ significantly on pre-banding social and physical quality of life, but the conversion group showed a worse pre-banding mental quality of life, as reflected in significantly lower scores on the subscales ‘emotional role limitations’ (p < 0.05) and ‘mental health’ (p < 0.05), and a just not significant lower score on the MCS score (p = 0.05). The pre-banding differences between groups that were significant were moderate to large with effect sizes varying between 0.71 and 0.77 (Cohen’s d). Also repeated measures analyses of variance that examined quality of life across all measurements showed lower levels on the subscales ‘emotional role limita-
Conversion to Gastric Bypass in Patients with Unsuccessful Weight Loss after Gastric Banding

This is the first study to examine a psychological characteristic of patients who did or did not undergo conversion to gastric bypass for unsuccessful weight loss following gastric banding. The mental quality of life of patients who had a conversion to gastric bypass proved to be enduringly worse compared to those who did not have a conversion. Our results suggest that a low mental quality of life is a signal for further intervention.

We expected that a worse quality of life could be a ‘cue to action’ [7, 8], in this case conversion to gastric bypass. Notably, we found a significant effect for mental quality of life, but not physical or social functioning. This may suggest that especially psychologically distressed patients are more likely to seek additional surgical treatment or to accept conversion to gastric bypass when it is offered. Another hypothesis is that patients with relatively good mental strength do not choose gastric bypass, because they believe that they are still capable to restrict food intake with the help of the gastric band. Besides the decisions of the patient, also decisions of the surgeon may play a role. Perhaps the decision to offer gastric bypass as
an additional intervention is postponed for patients who are considered to have relatively high mental strength.

Our study has some limitations. First, we have no insight into the hypothesized mechanisms underlying the finding that ‘unsuccessful’ patients with a relatively stable low mental health undergo conversion. Second, the sample size is small, although it was large enough to detect a moderate to large group difference in mental quality of life. Third, although our results convincingly indicate relative stability in mental health among our groups, we have no information on mental quality of life just before conversion. It would be useful to eventually develop a pre-operative algorithm to prevent conversions and let some patients have a gastric bypass from the beginning. Our study suggests that quality of life could be part of such an algorithm. Future studies should repeat our study results in larger samples and examine the hypothesized mechanisms underlying our finding. Overall, the bariatric team and patients should be aware that patient’s mental health may play a role in the decision for conversion to gastric bypass.
