We present a study of the dijet invariant mass spectrum in events with two jets produced in association with a W boson in data corresponding to an integrated luminosity of 4.3 fb$^{-1}$ collected with the D0 detector at $\sqrt{s} = 1.96$ TeV. We find no evidence for anomalous resonant dijet production and derive upper limits on the production cross section of an anomalous dijet resonance recently reported by the CDF Collaboration, investigating the range of dijet invariant mass from 110 to 170 GeV/c$^2$. The probability of the D0 data being consistent with the presence of a dijet resonance with 4 pb production cross section at 145 GeV/c$^2$ is $8 \times 10^{-6}$.

PACS numbers: 12.15.Ji, 12.38.Qk, 13.85.Rm, 14.80.-j

The CDF Collaboration at the Fermilab Tevatron $p\bar{p}$ collider recently reported a study of the dijet invariant mass ($M_{jj}$) spectrum in associated production with $W \rightarrow \ell \nu$ ($\ell = e$ or $\mu$) at $\sqrt{s} = 1.96$ TeV with an integrated luminosity of 4.3 fb$^{-1}$ [1]. In that paper they present evidence for an excess of events corresponding to 3.2 standard deviations (s.d.) above the background expectation, centered at $M_{jj} = 144 \pm 5$ GeV/c$^2$ [1]. The CDF authors model this excess using a Gaussian peak with a width corresponding to an expected experimental resolution for the CDF detector [2] of 14.3 GeV/c$^2$. Assuming the excess is caused by a particle X with $B(X \rightarrow jj) = 1$, the CDF Collaboration reports an estimated production cross section of $\sigma(p\bar{p} \rightarrow WX) \approx 4$ pb.

Using 5.3 fb$^{-1}$ of integrated luminosity, the D0 Collaboration has previously set limits on resonant $b\bar{b}$ pro-
duction in association with a W boson in dedicated searches for standard model (SM) Higgs bosons in the WH → ℓνb̄b̄ channel \[3\]. The D0 Collaboration reported upper limits on σ(pp → WH) × B(H → b̄b̄) ranging from approximately 0.62 pb for M_H = 100 GeV/c² to 0.33 pb for M_H = 150 GeV/c². The CDF Collaboration has performed a similar search using 2.7 fb\(^{-1}\) of integrated luminosity and reported no excess of events \[4\]. Furthermore, the D0 Collaboration has not observed a significant excess of associated W boson and dijet production in analyses of either WW/WZ → (ℓνjj) \[5\] or H → WW → ℓνjj \[6\] using 1.1 fb\(^{-1}\) and 5.4 fb\(^{-1}\) of integrated luminosity, respectively.

In this Letter we report a study of associated W(→ ℓν) and dijet production using data corresponding to 4.3 fb\(^{-1}\) of integrated luminosity collected with the D0 detector \[7\] at \(\sqrt{s} = 1.96\) TeV at the Fermilab Tevatron pp Collider. The CDF study of this production process uses the same integrated luminosity. We investigate the dijet invariant mass range from 110 to 170 GeV/c² for evidence of anomalous dijet production.

To select W(→ ℓν) + j j candidate events, we impose similar selection criteria to those used in the CDF analysis: a single reconstructed lepton (electron or muon) with transverse momentum p_T > 20 GeV/c and pseudorapidity \(|η| < 1.0\); missing transverse energy E_T > 25 GeV; two jets reconstructed using a jet cone algorithm \[9\] with a cone of radius \(ΔR = 0.5\) that satisfy p_T > 30 GeV/c and \(|η| < 2.5\), while vetoing events with additional jets with p_T > 30 GeV/c. The separation between the two jets must be \(|Δη(\text{jet}_1, \text{jet}_2)| < 2.5\), and the azimuthal separation between the most energetic jet and the direction of the E_T must satisfy Δφ(jet, E_T) > 0.4. The transverse momentum of the dijet system is required to be p_T(jj) > 40 GeV/c. To reduce the background from processes that do not contain W → ℓν decays, we require a transverse mass \[10\] of M_T^μν > 30 GeV/c². In addition, we restrict M_T^μν < 200 GeV/c² to suppress muon candidates with poorly measured momenta. Candidate events in the electron channel are required to satisfy a single electron trigger or a trigger requiring electrons and jets, which results in a combined trigger efficiency for the \(eνjj\) selection of (98±2)%\%. A suite of triggers in the muon channel achieves a trigger efficiency of (95±5)% for the \(μνjj\) selection. Lepton candidates must be spatially matched to a track that originates from the pp interaction vertex of each MC sample are adjusted to match those in data. The p_T distribution of Z bosons is corrected at the generator level to reproduce dedicated measurements \[21\].

Other D0 analyses of this final state apply additional corrections to improve the modeling of the W+jets and Z+jets production in the MC \[3\]. For the results presented in this Letter, we choose not to apply those corrections in order to parallel the CDF analysis. We did, however, study the effects of applying such corrections \[21\] and find they do not alter our conclusions.

We consider the effect of systematic uncertainties on both the normalization and the shape of dijet invariant mass distributions. Systematic effects are considered from a range of sources: the choice of renormalization and factorization scales, the ALPGEN parton-jet matching algorithm \[22\], jet energy resolution, jet energy scale, and modeling of the underlying event and parton showering. Uncertainties on the choice of PDF, as well as uncertainties from object reconstruction and identification, are evaluated for all MC samples.
In Fig. 1 we present the dijet invariant mass distribution after a fit of the sum of SM contributions to data. Other distributions are available in the supplementary material. The fit minimizes a Poisson $\chi^2$-function with respect to variations in the rates of individual background sources and systematic uncertainties that may modify the predicted dijet invariant mass distribution. A Gaussian prior is used for each systematic uncertainty, including those on the normalization of each sample, but the cross sections for diboson and $W+\text{jets}$ production in the MC are floated with no constraint. The fit computes the optimal values of the systematic uncertainties, accounting for departures from the nominal predictions by including a term in the fit function that sums the squared deviation of each systematic in units normalized by its ±1 s.d. Different uncertainties are assumed to be mutually independent, but those common to both lepton channels are treated as fully correlated. We perform fits to electron and muon selections simultaneously and then sum them to obtain the dijet invariant mass distributions shown in Fig. 1. The measured yields after the fit are given in Table I.

To probe for an excess similar to that observed by the CDF Collaboration, we model a possible signal as a Gaussian resonance in the dijet invariant mass with an observed width corresponding to the expected resolution of the D0 detector given by $\sigma_{M_jj} = \sigma_{W\to jj} \cdot \sqrt{M_{jj}/M_{W\to jj}}$. Here, $\sigma_{W\to jj}$ and $M_{W\to jj}$ are the width and mass of the $W\to jj$ resonance, determined to be $\sigma_{W\to jj} = 11.7 \text{ GeV}/c^2$ and $M_{W\to jj} = 81 \text{ GeV}/c^2$ from a simulation of $WW\to \ell\nu jj$ production. For a dijet invariant mass resonance at $M_{jj} = 145 \text{ GeV}/c^2$, the expected width is $\sigma_{M_{jj}} = 15.7 \text{ GeV}/c^2$.

We normalize the Gaussian model in the same way as reported in the CDF Letter. We assume that any such excess comes from a particle $X$ that decays to jets with 100% branching fraction. The acceptance for this hypothetical process ($WX \to \ell\nu jj$) is estimated from a MC simulation of $WH\to \ell\nu b\bar{b}$ production. When testing the Gaussian signal with a mean of $M_{jj} = 145 \text{ GeV}/c^2$, the acceptance is taken from the $WH\to \ell\nu b\bar{b}$ simulation with $M_H = 150 \text{ GeV}/c^2$. This prescription is chosen to be consistent with the CDF analysis, which used a simulation of $WH\to \ell\nu b\bar{b}$ production with $M_H = 150 \text{ GeV}/c^2$ to estimate the acceptance for the excess that they observe at $M_{jj} = 144 \text{ GeV}/c^2$. When probing other values of $M_{jj}$, we use the acceptance obtained for $WH\to \ell\nu b\bar{b}$ MC events with $M_H = M_{jj} + 5 \text{ GeV}/c^2$.

We use this Gaussian model to derive upper limits on the cross section for a possible dijet resonance as a function of dijet invariant mass using the CL$_{s}$ method with a negative log-likelihood ratio (LLR) test statistic that is summed over all bins in the dijet invariant mass spectrum. Upper limits on cross section are calculated at the 95% confidence level (C.L.) for Gaussian signals with mean dijet invariant mass in the range $110 < M_{jj} < 170 \text{ GeV}/c^2$, in steps of 5 GeV/c$^2$, allowing the cross sections for $W+\text{jets}$ production to float with no constraint. Other contributions are constrained by the a priori uncertainties on their rate, either derived from

theory or subsidiary measurements.

The Gaussian model is assigned systematic uncertainties affecting both the normalization and shape of the distribution derived from the systematic uncertainties on the diboson simulation. A fit of both the signal+background and background-only hypotheses is performed for an ensemble of pseudo-experiments as well as for the data distribution. The results of the cross section upper limit calculation are shown in Fig. 2 and are summarized in Table II.

In a further effort to evaluate the sensitivity for any excess of events of the type reported by the CDF Collaboration, we perform a signal-injection test. We repeat the statistical analysis after injecting a Gaussian signal model, normalized to a cross section of 4 pb, into the D0 data sample, thereby creating a mock “data” sample modeling the expected outcome with a signal present. The size and shape of the injected Gaussian model for \( M_{jj} = 145 \text{ GeV/c}^2 \) relative to other data components is shown in Fig. 1.

The LLR metric provides a sensitive measure of model compatibility, providing information on both the rate and mass of any signal-like excess. We therefore study the LLR distributions obtained with actual data as well as the signal-injected mock data sample. The results of the LLR test in Fig. 3 show a striking difference between the two hypotheses, demonstrating that this analysis is sensitive to the purported excess. In the actual data, however, no significant evidence for an excess is observed.

In Fig. 4 we show as a function of cross section the \( p \)-value obtained by integrating the LLR distribution populated from pseudo-experiments drawn from the signal+background hypothesis above the observed LLR, assuming a Gaussian invariant mass distribution with a mean of \( M_{jj} = 145 \text{ GeV/c}^2 \). The \( p \)-value for a Gaussian signal with cross section of 4 pb is \( 8.0 \times 10^{-6} \), corresponding to a rejection of this signal cross section at a Gaussian equivalent of 4.3 s.d. We set a 95% C.L. upper limit of 1.9 pb on the production cross section of such a resonance.

In summary, we have used 4.3 fb\(^{-1}\) of integrated luminosity collected with the D0 detector to study the dijet invariant mass spectrum in events containing one \( W \to \ell \nu \) (\( \ell = e \) or \( \mu \)) boson decay and two high-\( p_T \) jets. Utilizing a similar data selection as the CDF Collaboration we find no evidence for anomalous, resonant

production of dijets in the mass range $110 - 170$ GeV/$c^2$. Using a simulation of $W H \rightarrow \ell \nu b\bar{b}$ production to model acceptance and efficiency, we derive upper limits on the cross section for anomalous resonant dijet production. For $M_{jj} = 145$ GeV/$c^2$, we set a 95% C.L. upper limit of 1.9 pb on the cross section and we reject the hypothesis of a production cross section of 4 pb at the level of 4.3 s.d.

[8] D0 uses a spherical coordinate system with the z axis running along the proton beam axis. The angles $\theta$ and $\phi$ are the polar and azimuthal angles, respectively. Pseudorapidity is defined as $\eta = -\ln [\tan(\theta/2)]$, in which $\theta$ is measured with respect to the proton beam direction.
[9] G. C. Blazey et al., arXiv:hep-ex/0005012 (2000). The seeded iterative mid-point cone algorithm with radius $\Delta R = \sqrt{(\Delta \phi)^2 + (\Delta y)^2} = 0.5$ was used.
APPENDIX

Fit of a 145 GeV/c² Dijet Resonance

The D0 data do not indicate the presence of a non-SM dijet resonance such as indicated by the CDF Collaboration. In the Letter we showed the fit of the SM predictions to the data. However, fitting only the SM contributions could hide an excess if the systematic uncertainties allowed the SM contributions to be distorted in such a way that they filled in the excess. To study this question, we present a fit to the data of the SM predictions plus the Gaussian signal template with $M_{jj} = 145$ GeV/c². The resulting dijet mass distribution is shown in Fig. 4. The fit is performed in the same way as described in the Letter (no constraint on diboson or $W$+jets normalizations), except that it now also includes the Gaussian signal template for $M_{jj} = 145$ GeV/c² with a freely floating normalization. The Gaussian model includes systematic uncertainties affecting both the normalization and shape of the template, analogous to the systematic uncertainties for the diboson prediction. The best fit value for the Gaussian template yields a cross section of $\sigma(p\bar{p} \to WX) = 0.82^{+0.82}_{-0.82}$ pb, consistent with no excess. When we fix the diboson cross section to the SM prediction with a Gaussian prior of 7% on the rate, the best fit value for the Gaussian template yields a cross section of $\sigma(p\bar{p} \to WX) = 0.42^{+0.76}_{-0.42}$ pb.

Kinematic Corrections to the Simulation

The common tools used to simulate the predicted SM contributions perform well in general, but they have shortcomings. For example, different event generators have different predictions for production angles and relative angles between jets in $W$+jets and $Z$+jets events. Thus, it is not unexpected that the simulated $W$+jets and $Z$+jets samples do not perfectly model the angular distributions of jets. For analyses with looser selections, such as the search for $WH$ production at D0, these jet angular distributions show clear discrepancies between data and the simulated $W$+jets and $Z$+jets events. Thus, these analyses use parameterized functions to correct the pseudorapidities of the two highest $p_T$ jets and the $\Delta R = \sqrt{(\Delta \eta)^2 + (\Delta \phi)^2}$ separation between those two jets in $W/Z$+jets samples, and the transverse momentum of the $W$ boson candidate, $p_T(W)$, in the $W$+jets samples, to better model the data.

The tight kinematic selection criteria employed in this analysis (e.g., $p_T(jj) > 40$ GeV/c²) remove much of the phase space in which the MC generators have difficulty modeling data (e.g., low $p_T(W)$), greatly reducing the need for the kinematic corrections of the simulation. Therefore, the plots and results in the Letter do not use any of these kinematic corrections, which is consistent with the CDF analysis.

Although kinematic corrections are not required to achieve adequate modeling when applying the tight selection criteria of this analysis, modeling issues are probably still present. In this section we present the results obtained when the kinematic corrections (derived from a selection similar to the search for $WH$ production) are applied to this analysis.

The following figures are analogous to those in the Letter, except that the above mentioned kinematic corrections have been applied to the simulation. Figure 5 shows the dijet invariant mass distribution after the fit of the simulation has been applied to the data (a) without and (b) with subtraction of SM contributions other than from the SM diboson processes, along with the ±1 s.d. systematic uncertainty on all SM predictions.

Kinematic distributions presented in this Section are modeled without the additional corrections applied to the MC. Figure 9 shows the dijet invariant mass distribution for the separate lepton channels after the simultaneous fit in these two distributions of the SM predictions to data. Figure 1(a) in the Letter is the combination of these two plots. Figure 10 shows comparisons between data and simulation for other kinematic variables after the fit.

Additional Data-MC Comparisons

Kinematic distributions presented in this Section are modeled without the additional corrections applied to the
