Soluble IL-18 receptor complex: a new star in the firmament of rheumatoid arthritis diagnosis?

Fons AJ van de Loo*

Abstract

It has long been recognized that laboratory tests are useful in the diagnosis of disease and to monitor treatment outcome. Their performance has become even more demanding with the development of personalized medicine. In patients with rheumatoid arthritis (RA) the standard biochemical tests measure serological markers of disease, such as C-reactive protein, and RA-associated auto-antibodies, such as rheumatoid factor and anti-citrullinated protein antibodies. The information obtained from these markers does not, however, provide a complete picture of the disease and treatment efficacy. New biomarkers based on cytokine receptor complexes are promising for RA theragnostics.

Rheumatoid arthritis biomarkers

With the success of biologicals in the treatment of rheumatoid arthritis (RA), such as infliximab, adalimumab (anti-TNF), rituximab (anti-B-cell), and tocilizumab (anti-IL-6), the armamentarium of physicians is expanding so that personalized medicine is within our reach. The study of Satoko Takei and colleagues [1] in this issue of Arthritis Research & Therapy describes a new serum biomarker with clear potential of becoming a valuable tool for the pharmaco diagnosis of RA. Biomarker tests that are currently available are failing to guide therapeutic decision making. C-reactive protein (CRP) and serum amyloid protein are sensitive markers of disease activity but blood levels often do not correlate with the obtained therapeutic effect. The same holds true for IgM rheumatoid factor and especially for anti-cyclic citrullinated protein antibodies, although the latter are specific for RA and of great prognostic value for the outcome of disease [2]. It is important to monitor disease activity during therapy in order to adjust, change or even stop therapy when necessary. This is the reason that the search for new biomarkers that can be used to monitor or even predict therapeutic effectiveness is still ongoing.

Biomarkers identified by -omics

The major problem is that RA is a heterogeneous disease, with disease course and extent of connective tissue destruction varying considerably among patients. Histological evaluation of the inflamed synovium confirms the heterogeneity in RA, and cDNA microarray analysis of synovial tissue showed that, for example, STAT1 (signal transducing and activator of transcription-1) gene expression distinguishes between RA subtypes [3]. For the diagnosis and management of disease, however, the genetic analysis of the inflamed synovial tissue is cumbersome. Blood is a highly dynamic environment, communicating with practically every tissue in the body, and is thus proposed as a ‘sentinel tissue’ that reflects disease progression in the body. Blood not only transports soluble biomarkers but because the leukocytes interact and communicate with practically every tissue, they bear rich information regarding inflammation and immune responses. Whole genome expression profiling of blood cells from RA patients has identified marker genes the expression of which predicts with 86% accuracy the response of infliximab in RA [4]. More importantly, only eight marker genes are needed to evaluate blood cells for a valid prediction. Another study showed that the expression of CD11c is a biomarker in monocytes to identify responders to abdalumimab [5]. Interestingly, the correlation of CD11c with response was lost when methotrexate was co-administered, showing the narrow window of CD11c as a predictive transcriptional biomarker. Many other genes are significantly upregulated in RA peripheral blood mononuclear cells compared to healthy controls - for example, those encoding CD14 antigen, defensin-a1/3, and S100A proteins, which are of potential diagnostic and prognostic value for RA. Over the past decade, proteomics have yielded potential new

The serum levels of this complex were significantly higher in patients with RA and adult-onset Still's disease than in healthy controls and osteoarthritis and systemic lupus erythematosus patients. Moreover, treatment of RA patients with the TNF inhibitor etanercept resulted in a significant improvement in serum levels of soluble IL-18Rα complex. It remains to be seen whether the soluble IL-18Rα complex can be used for the evaluation of joint damage or disease activity but even so it could be useful for the diagnosis of RA. The soluble IL-18Rα complex as a biomarker may capture the complexity of the inflammatory process: the shedding of membrane IL-18Rα as a marker of enhanced proteolytic activity; the activation and release of IL-18 by the inflammasome as a marker of innate immunity; and the alternatively spliced soluble IL-18Rβ, which is mainly expressed in the lymphoid organs and regulates IL-18-driven T-cell immunity [10]. Currently, CRP is still a useful and reliable marker for disease activity and treatment response in the clinic. However, it is recognized that combinations of biomarkers will greatly enhance the power for diagnosis and the soluble IL-18Rα complex may be useful in this regard for RA, but longitudinal studies and cross-sectional analysis are warranted.

**Abbreviations**
CRP, C-reactive protein; IL, interleukin; IL-18R, interleukin-18 receptor; RA, rheumatoid arthritis; TNF, tumor necrosis factor.
