(Dated: February 2, 2008)

A pulsed beam of ground state OH radicals is slowed down using a Stark decelerator and is subsequently loaded into an electrostatic trap. Characterization of the molecular beam production, deceleration and trap loading process is performed via laser induced fluorescence detection inside the quadrupole trap. Depending on details of the trap loading sequence, typically $10^5$ OH ($X^2\Pi_{3/2}$, $J = 3/2$) radicals are trapped at a density of around $10^7$ cm$^{-3}$ and at temperatures in the 50-500 mK range. The 1/e trap lifetime is around 1.0 second.

Getting ever better control over both the internal and external degrees of freedom of gas-phase molecules has been an important theme in molecular physics during the last decades. This control is important, for instance, in spectroscopic investigations, in collision and reactive scattering experiments and in photo-dissociation, or half-collision, studies. Seeded molecular beams, both continuous and pulsed, have been extensively used to produce samples of molecules in only the lowest internal energy states, with typical rotational temperatures of a few K. In these molecular beams the longitudinal velocity distribution is also well defined, and translational temperatures of around 1 K are obtained in the moving frame of the molecular beam. Further control over the molecules is achieved when their orientation in space is actively manipulated, using either static electro-magnetic fields and/or radiation fields. Sophisticated and powerful detection schemes have been developed to experimentally study (half-) collisions and reactions of the thus prepared molecules in the required detail.

Over the last years our group has been developing methods to get improved control over the absolute velocity and over the velocity spread of molecules in a molecular beam. These methods rely on the, quantum-state specific, force that polar molecules experience in electric fields. This force is rather weak, typically some eight to ten orders of magnitude weaker than the force that the corresponding molecular ion experiences in the same electric field. This force nevertheless suffices to achieve complete control over the motion of polar molecules, using techniques akin to those used for the control of charged particles. We have explicitly demonstrated this by the construction of two types of linear accelerators, a buncher, a trap and a storage ring for neutral polar molecules. Using these tools, state-selected molecular beams with a computer-controlled absolute velocity and with record-low (longitudinal) temperatures have been produced. This holds great promise for the use of decelerated molecular beams in metrology, i.e., in experiments aimed at testing fundamental symmetries.

To be able to exploit the possibilities that these new tools offer for collision and reactive scattering experiments, the fraction of the pulsed molecular beam that is decelerated and/or trapped needs to come closer to unity, i.e., the 6-dimensional phase space acceptance of the various elements needs to be increased to better match to the typical emittance of a molecular beam. In addition, deceleration and trapping needs to be performed on those molecules that are of most relevance in collision and reactive scattering experiments; thus far, electrostatic trapping after Stark deceleration has only been demonstrated for ND$_3$ molecules.

We here report the deceleration and electrostatic trapping of ground state OH ($X^2\Pi_{3/2}$, $J = 3/2$) radicals. The experiments are performed in a new generation molecular beam deceleration machine, designed such that a large fraction of the molecular beam pulse can be slowed down and trapped. The role of the omnipresent OH radical as intermediate in many chemical reactions has made this a benchmark molecule in collision and reactive scattering studies. Hexapole state-selection and focusing, e.g., transverse phase space manipulation, of a beam of OH is well documented and often used in these studies. The possibility to manipulate the longitudinal phase-space distribution of OH radicals inside a decelerator has recently been demonstrated as well.

The experimental setup is schematically shown in Fig. A pulsed beam of OH with a mean velocity of 460 m/s and with a velocity spread of 15 % (full width half maximum, FWHM) is produced via ArF-laser dissociation of HNO$_3$ seeded in Kr near the orifice of a pulsed valve. Production thus takes place at a well-defined time and at a well-defined position, which is ideal for coupling the molecular beam into the decelerator. More than 95 % of the OH radicals in the beam reside in the lowest rotational and vibrational level of the $X^2\Pi_{3/2}$ spin-orbit manifold of the electronic ground state. This population is distributed over the two A-doublet components of the $J = 3/2$ level, which has a zero-field splitting of 0.055 cm$^{-1}$. Only OH radicals in low-field seeking quan-
FIG. 1: Scheme of the experimental setup. The longitudinal phase space acceptance of the decelerator for OH (\(J = 3/2, |M_J\Omega| = 9/4\)) is given for three different phase angles \(\phi_0\), together with the longitudinal phase space distribution of the OH beam at the entrance of the decelerator (shaded area). The observed LIF signal as a function of time after OH is observed. The main portion of the OH beam is transported through the machine as a compact package (less than 25 \(\mu\)s FWHM in the TOF profile), independent of the length of the decelerator. The TOF profile resulting from a three-dimensional trajectory calculation, shown underneath the measurement, quantitatively reproduces the observation. From the calculations, the contributions of the individual \(|M_J\Omega|\) components to the TOF profile can be identified. In addition, these calculations enable a detailed understanding of the untrapped dynamics in the deaccelerator, which manifests itself by the features in the wings of the observed TOF profile.

The electrostatic trap consists of a ring electrode, centered 21 mm downstream from the last electrodes of the decelerator, with an inner radius \(R\) of 10 mm and two hyperbolic end-caps with a half-spacing of \(R/\sqrt{2}\). This trap is scaled up by a factor two compared to the trap that we have used thus far [12]. The molecular beam enters the trap through a 4 mm diameter hole in the first end-cap. This hole is the only vacuum connection between the deceleration chamber and the trap chamber.
The hole in the TOF profile of the fast beam due to the disappearance of OH radicals that are decelerated is indicated by an arrow. In the measurement shown in the middle curve, OH radicals with an initial velocity around 440 m/s are decelerated to 170 m/s, operating the decelerator at a phase angle of $\phi_0 = 70^\circ$. In the lower curve, the observed TOF profile is shown when the decelerator operates at $\phi_0 = 77^\circ$, extracting about 1.2 cm$^{-1}$ of kinetic energy per deceleration stage. OH radicals with an initial velocity of 428 m/s ($E_{kin} = 130$ cm$^{-1}$) exit the decelerator with a velocity of around 21 m/s. The OH radicals in the non-decelerated part of the beam also experience the switched electric fields inside the decelerator. This leads to a highly structured phase-space distribution and results in rich oscillatory structure on the TOF profile of the fast beam, as shown enlarged in the figure. The slow beam of OH radicals is loaded into the electrostatic trap with voltages of 7 kV, 15 kV and -15 kV on the first end-cap, the ring electrode and the second end-cap, respectively. This creates a potential hill in the trap that is higher than the remaining kinetic energy of the molecules. The OH radicals therefore come to a standstill near the center of the trap, around 7.4 ms after their production. At that time, indicated by an arrow in Fig. 2, the first end-cap is switched from 7 kV to -15 kV to create a (nearly) symmetric 500 mK deep potential well. After some initial oscillations, a steady LIF signal is observed from the OH radicals in the trap. The LIF intensity of the trapped OH radicals is about 20 % of the peak LIF intensity of the non-decelerated beam of OH that passes through the trap. The observed LIF signal of the trapped OH radicals corresponds to a total number of about $10^5$ OH ($J = 3/2$, $|M_J\Omega| = 9/4$) radicals, in the approximately 0.03 cm$^3$ detection volume in the trap. In the inset, the LIF signal intensity is shown on a longer time-scale, from which a 1/e trap lifetime on the order of 1.0 second, limited by collisions with background gas, is deduced.

The absolute number of OH radicals that can be trapped as well as the phase space distribution of the trapped molecules critically depends on the details of the trap loading sequence. In Fig. 3 measurements are shown for two slightly different trap loading conditions, referred to as case A and case B. Curve A(i) and B(i) show the TOF profile of the slow beam of OH radicals that passes through the trap when no voltages are applied to the trap electrodes. Due to the lower beam velocity of around 15 m/s in case B compared to the 21 m/s in case A, the beam arrives later at the center of the trap, is spread out more and has a lower peak density. Curve A(ii) and B(ii) show the TOF profile when the voltages for trap loading as given earlier are constantly applied to the trap electrodes. In case A the molecules enter the trap too fast, and move past the center of the trap; the observed double-hump structure in the TOF profile is to be interpreted as the signal from both the incom-
a molecular beam deceleration and trapping machine that is designed such that almost the complete molecular beam pulse that passes through the skimmer in the right quantum-state can be transported through the trap at a tunable absolute velocity while staying together as a compact package. Alternatively, a sizeable fraction of this molecular beam pulse can be slowed down to a near standstill and loaded into the electrostatic trap, where the molecules can then be trapped up to seconds. Sensitive quantum-state specific detection of the molecules can be performed inside the quadrupole trap. As the molecular beam machine typically runs at a 10 Hz repetition rate, and as different high voltage switching sequences can be applied to adjacent molecular beam pulses, this together offers the unique possibility to perform “in-beam” collision and reactive scattering experiments as a function of the continuously tunable collision energy and with an unprecedented energy resolution.
