The binding of carbon monoxide to iron, ruthenium, rhenium, and tungsten clusters is studied by means of infrared multiple photon dissociation spectroscopy. The CO stretching mode is used to probe the interaction of the CO molecule with the metal clusters and thereby the activation of the C–O bond. CO is found to adsorb molecularly to atop positions on iron clusters. On ruthenium and rhenium clusters it also binds molecularly. In the case of rhenium, binding is predominantly to atop sites, however higher coordinated CO binding is also observed for both metals and becomes prevalent for rhenium clusters containing more than nine atoms. Tungsten clusters exhibit a clear size dependence for molecular versus dissociative CO binding. This behavior denotes the crossover to the purely dissociative CO binding on the earlier transition metals such as tantalum.

I. INTRODUCTION

The binding of carbon monoxide to transition metals has been widely studied due, in part, to its technological importance, e.g., the Fischer–Tropsch synthesis for the production of synthetic fuels. For a metal to be an appropriate catalyst, it must bind to carbon monoxide sufficiently strongly to weaken the CO triple bond. However, the interaction of the metal with either carbon or oxygen must be sufficiently weak in order to allow for subsequent reactions. This is generally fulfilled by the elements in the middle of the transition metal series and leads, for instance, to the high activity of rhenium and cobalt for CO methanation. These metals mark the transition from dissociative to molecular binding of CO for the 3d and 4d metals, respectively. According to Brodén et al., dissociative CO binding is found at room temperature for the metals left of a diagonal through the periodic system formed by the elements cobalt, ruthenium, and rhenium. For all metals we previously studied, it is seen that the transition from dissociative to molecular binding of carbon monoxide to surfaces also holds for CO bound to gas-phase metal clusters. Carbon monoxide binds dissociatively to clusters of the early transition metals V (Ref. 5) and Nb, but molecularly to clusters of Co, Rh, Ni, Pd, Pt, and Au.

The interplay of bond formation between CO and the metal and the activation of the C–O bond is classically described within the Blyholder model. The CO 5σ orbital interacts with initially unoccupied d orbitals of the metal center (σ donation), while filled metal d orbitals interact with the CO π∗ orbital (π back bonding). The strength of the back bonding, and the related weakening of the C–O bond, depends on the number of metal atoms the CO is bound with and the electron density at the metal center. As the C–O bond strength is sensitive to the binding site on metals, the CO-metal system is often studied as a useful model to characterize binding sites at metal centers. The relative strength of the C–O bond can be conveniently probed via vibrational spectroscopy; for gas-phase cluster complexes this information can be obtained by means of infrared multiple photon dissociation (IR-MPD) spectroscopy.

Using this technique it has been found that CO binds to clusters of the late 3d metals only at atop sites, but for rhodium and palladium clusters also to more coordinated sites. For the 5d metals Pt and Au, again only binding to atop sites is observed. Going from CO binding to atop sites, via bridge sites, to hollow sites on the metal clusters typically redshifts the observed C–O stretching frequency, ν(CO), approximately by 150 cm⁻¹. For any given cluster size, ν(CO) redshifts going from cationic to neutral to anionic clusters due to the increase in electron density on the metal and stronger back bonding. Although this shows that the degree of C–O activation depends on the charge state of the clusters, there are no indications so far for differences in the overall molecular or dissociative binding of CO with cationic, neutral, or anionic clusters of the same metal. Here we will focus on CO interaction with clusters of Fe, Ru, Re, and W to probe the transition region for molecular versus dissociative binding of CO to clusters of transition metals, and to compare this to the behavior of CO on extended surfaces.

II. EXPERIMENTAL TECHNIQUES

The IR-MPD spectra are obtained using one of two cluster beam setups. One is equipped with a pulsed gas flow and was used primarily for ionic clusters, while the second, which employs a cluster source with a continuous flow of helium gas, was used for neutral metal clusters. The range of cluster sizes and charge states reported here was determined by the ability of these two sources to produce usable cluster signal. This varies from metal to metal. For these reasons, only neutral iron and tungsten clusters and ionic ruthenium and rhenium clusters have been investigated in this study.

Metal atoms are produced in both experiments by laser ablation (frequency doubled Nd:YAG laser, 532 nm) of a rotating metal rod. The atoms cluster and are carried in either a short pulse of He gas or a continuous flow. Carbon monoxide is subsequently introduced downstream of a short pulse of He gas or a continuous flow. Carbon monoxide is subsequently introduced downstream of a short pulse of He gas or a continuous flow. The atoms cluster and are carried in either a rotating metal rod. The atoms cluster and are carried in either a short pulse of He gas or a continuous flow. Carbon monoxide is subsequently introduced downstream of a short pulse of He gas or a continuous flow. The reaction stops by expansion into vacuum and a molecular beam forms, which passes through a skimmer and a 1 mm aperture. In the detection chamber, the ions are accelerated by a pulsed electric field and detected by a reflectron time-of-flight mass spectrometer (Jordan TOF Products). In the study of neutral clusters, a potential is applied to the aperture to deflect ionic species, and 7.9 eV photons emitted by an F2 laser ionize the neutral clusters in a static electric field. Care is taken to ensure the laser fluence is sufficiently low to avoid fragmentation induced by absorption of multiple UV photons.

Mass spectra are collected with and without interaction with an IR beam delivered by the Free Electron Laser for Infrared eXperiments (FELIX). A resonance of the IR radiation with the carbon monoxide stretching frequency of a complex can lead to the absorption of multiple IR photons and the fragmentation of CO from the metal clusters. FELIX is typically run with macropulse energies of ~7 mJ at 2000 cm⁻¹, a macropulse duration of 5 μs, and is scanned over the frequency range expected for the stretching vibrations of CO on metal clusters (typically 1500–2100 cm⁻¹). IR depletion spectra are constructed from the IR frequency dependence of the intensity ratio of a given mass peak with and without FELIX radiation. As this detection method is mass sensitive, the IR depletion spectra for all CO-metal cluster complexes are measured simultaneously. Consequently, the quality of depletion spectra is highly dependent on cluster signal, mass distribution, FELIX performance, as well as other factors. Spectra reported here have spectral bandwidths similar to those reported previously for CO molecularly bound to different transition metal clusters. Absorption of multiple photons can lead to spectral shifts in peak positions, but the shifts are caused by cross anharmonicities, they are expected to be small and within the linewidth of the IR laser (~20 cm⁻¹ full width at half maximum).

III. RESULTS AND DISCUSSION

A. Iron

The IR-MPD spectra of CO bound on neutral Feₙ clusters (n=18–30) show a single absorption band around 1865 cm⁻¹ for all cluster sizes (Fig. 1). The intensity of the CO complexes in the mass spectra can be depleted by up to 60–80% in these bands. This allows the conclusion that these bands originate from the dominant species of iron cluster CO complexes, even though only a relatively narrow frequency range (1775–1950 cm⁻¹) has been scanned. The bands can be unambiguously assigned to a C–O stretching vibration for CO bound to the metal cluster since oxide and carbide species formed by dissociation of CO on iron surfaces absorb between 400 and 550 cm⁻¹. The stretching frequencies of the diatomic FeC and FeO species are in the 800–900 cm⁻¹ region, and pure iron clusters are predicted to have absorptions below 400 cm⁻¹. Hence, it can be concluded that for the major species carbon monoxide binds molecularly to neutral iron clusters. Although we can safely make this conclusion for the major species in the molecular beam, we must also note that we do not achieve 100% depletion in the spectra. This could be simply due to a nonperfect overlap of molecular beam and IR laser. However, it is also possible that a second structural isomer which does not absorb radiation in this spectral range (i.e., dissociatively bound CO on the iron clusters) may also be present in the molecular beam.

It is difficult to assign the CO adsorption site by direct comparison to CO adsorbed on iron surfaces because of diverse and partly inconsistent assignments for the vibrational bands of CO absorbed on iron surfaces (see below). There-
Therefore, we base our assignment on established trends in CO binding to metal clusters. In general, one expects a stronger activation of the C–O bond on iron as compared to later transition metals for the same binding geometry. A decrease in the C–O bond strength and the accompanying decrease in \( \nu(\text{CO}) \) with decreasing atomic number, within a row of transition metals is seen for CO bound to atop sites on clusters of the 3d metals cobalt (1940 cm\(^{-1}\)) and nickel (1994 cm\(^{-1}\)) and also for the 4d metals rhodium (1960 cm\(^{-1}\)) and palladium (\(\sim\)2000 cm\(^{-1}\)).\(^7\) Following the trend along the 3d transition metal series, we would expect the atop bound CO to iron clusters to show an absorption band slightly below 1900 cm\(^{-1}\). The observed C–O stretching frequencies around 1865 cm\(^{-1}\) are in reasonable agreement with this prediction, and can on this basis be assigned to CO bound to atop sites on the neutral iron clusters. If CO were twofold bound to the iron clusters, we would expect the absorption to be redshifted an additional 150–200 cm\(^{-1}\).

This assignment is fully inline with earlier ones. The stretching frequency of gas phase CO bound to a single Fe atom is found at 1946 cm\(^{-1}\) and CO adsorbed at low coverage to atop sites on Fe(110) has a vibrational frequency of 1890 cm\(^{-1}\)\(^\text{21,22}\). In our previous studies on CO adsorption to neutral cobalt and rhodium clusters the stretching frequency for atop bound CO on the clusters was systematically redshifted from values reported for CO bound to a single atom or adsorbed to surfaces by 30–70 cm\(^{-1}\)\(^7\), and we now find a similar shift for iron clusters.

However, bands at much higher frequencies have also been assigned to atop bound CO on other iron surfaces. For instance, for CO on Fe(111) three vibrational bands at 2000, 1805, and 1530 cm\(^{-1}\) were assigned to C–O stretching frequencies for carbon monoxide bound to atop, shallow hollow, and deep hollow sites on the surface, respectively.\(^23\) CO on Fe(100) has been suggested to be tilted or side-on bound yielding a very low \( \nu(\text{CO}) \) frequency around 1200 cm\(^{-1}\) at low coverage, whereas binding to twofold hollow sites (2020 cm\(^{-1}\)) or on atop sites (2070 cm\(^{-1}\)) was concluded to occur at higher coverage.\(^18,24–26\)

These frequencies appear very high compared to the 1865 cm\(^{-1}\) we assign to atop bound CO adsorbed to iron clusters. They are also high compared to the values calculated for atop bound CO species on extended iron surfaces at low coverage, which are in the 1880–1920 cm\(^{-1}\) range.\(^27–29\) As the bands above 2000 cm\(^{-1}\) appear only at higher CO coverage on the surfaces, it might be that they are not due to isolated CO molecules but related to the presence of geminal carbonyls formed at low coordinated Fe atoms at steps or defects. Slab model calculations studying the mechanism of Fe(CO)\(_3\) formation on Fe(100) find that geminal binding can energetically compete with the formation of CO ligands.\(^30\) The reduced back bonding leads to an upshift of \( \nu(\text{CO}) \) just as in polynuclear iron carbonyls where geminal atop bound CO ligands have their bands typically between 2020 and 2080 cm\(^{-1}\).\(^31,32\)

There has been a comprehensive DFT study of CO bound on small gas-phase iron clusters.\(^33\) It predicts that two-, three-, and fourfold coordinated CO species form the most stable binding geometry in Fe\(_2\), Fe\(_3\), Fe\(_4\), and Fe\(_5\), repectively. The reported CO stretching frequencies for these species are significantly below our experimental values for CO atop bound to Fe\(_{18–30}\), as would be expected. Unfortunately, we were unable to measure clusters this small to confirm the transition from high coordination binding in small clusters to atop binding in large clusters, which has some parallels in rhodium cluster CO complexes.\(^8\)

### B. Ruthenium

In the case of ruthenium clusters, we studied the interaction of CO with the cationic and anionic species containing 4–19 Ru atoms. Infrared spectra of carbon monoxide adsorbed on ionic ruthenium clusters are shown in Fig. 2. The highest frequency bands are observed at \(\sim\)2000 cm\(^{-1}\) on cationic ruthenium clusters, and around 1870 cm\(^{-1}\) for anionic clusters.

Assignments of the observed bands can be made by comparison with \( \nu(\text{CO}) \) values for CO bound to extended ruthenium surfaces. For rhodium clusters (one element to the right of Ru in the Periodic Table), we found that \( \nu(\text{CO}) \) for carbon monoxide adsorbed to larger (\(n \geq 10\)) cationic clusters tends to be close to surface values.\(^7\) As the stretching frequencies for atop bound CO on ruthenium surfaces are reported to be in the 1980–2010 cm\(^{-1}\) region,\(^34–39\) the higher frequency bands for CO adsorbed on cationic ruthenium clusters are assigned to atop bound CO. Also, the cationic RuCO\(_+\) complex has a C–O stretching frequency of 2135 cm\(^{-1}\) in a neon matrix,\(^40,41\) and for larger cationic clusters this frequency should shift to the red as more ruthenium atoms become available to delocalize the positive charge.\(^7\) For anionic clusters containing about 10 Ru atoms \( \nu(\text{CO}) \)
assigned to atop bound CO is redshifted from the cationic counterpart by roughly 100–150 cm\(^{-1}\), which is very similar to the shift observed for rhodium clusters.\(^7\)

In Fig. 2, a second set of absorption bands is apparent around 1800 cm\(^{-1}\) for the cationic clusters Ru\(_{10}\)CO\(^+\), Ru\(_{12}\)CO\(^+\), and Ru\(_{16}\)CO\(^+\), and at 1740 and 1711 cm\(^{-1}\) for Ru\(_{15}\)CO\(^-\) and Ru\(_{13}\)CO\(^-\), respectively. As the predictions for \(\nu(CO)\) for atop and bridge sites on Ru(0001) are separated by approximately 170 cm\(^{-1}\),\(^42\) the redshift of about 200 cm\(^{-1}\) from the bands assigned to atop CO on ruthenium clusters leads us to assign the second set to CO bound to bridge sites. It is interesting to note that the bridge bounded carbonyls are observed for the same sized anions and cations. This might point to common geometric arrangements of these clusters and a structural reason for the appearance of bridge bound CO ligands.

It is remarkable that the C–O stretching frequency for carbon monoxide adsorbed to odd numbered ruthenium clusters usually is observed at lower frequencies than for clusters with an even number of ruthenium atoms (see Fig. 2). This is particularly striking for \(\nu(CO)\) assigned to atop bound CO to cationic clusters containing 7–17 Ru atoms, where the separation is 30–100 cm\(^{-1}\); for the anionic clusters the difference is only approximately 15 cm\(^{-1}\). A similar shift is observed for \(\nu(CO)\) assigned to bridge bound CO; complexes exhibiting a low value for atop-\(\nu(CO)\) also show a low frequency for bridge-\(\nu(CO)\). Such a pronounced size dependence in \(\nu(CO)\), which is very different to the gradual shift related to the charge dilution in ionic clusters, has not been detected for other metals before. We considered multiple possible explanations for the observed shifts in the frequency based on predicted trends in the electronic and structural properties. However, most of these predictions are based on the assumption of cubic cluster structures,\(^43,44\) which may not be the real ground-state structures but merely an artifact of neglecting exact exchange in the density functional theory calculations.\(^45,46\) Clearly, a better understanding of the bare ruthenium clusters is required before an explanation of the observed trends in \(\nu(CO)\) can be given.

C. Rhenium

According to Brodèn, rhenium should be the lightest 5\(d\) metal to which CO binds molecularly.\(^3,4\) Indeed, the IR depletion spectra for cationic rhenium clusters containing up to 13 Re atoms complexed with carbon monoxide (Fig. 3) reveal the presence of molecularly bound CO. Here, we show the spectra of complexes with two CO molecules as well, as some bands are hardly visible in the complex with a single CO molecule but become more apparent in the complex with two CO molecules. The overall behavior, including the observed \(\nu(CO)\) values, is very similar in the complexes with one and two CO ligands.

Absorption bands are observed at three distinctly different regions in the spectra depending on cluster size (Fig. 3). Bands appear in the 1900–2070 cm\(^{-1}\) region (the absorption peaks for Re\(_7\) and Re\(_{11–13}\) are more pronounced when two CO ligands are bound to the clusters), which show a noticeable redshift with increasing cluster size. Again, these \(\nu(CO)\) values are similar to the CO stretching frequency for carbon monoxide adsorbed on an atop position to Re(0001) surfaces, which appears at 1990 cm\(^{-1}\) at low coverage.\(^47\) Hence, these high frequency absorptions are again most likely due to CO atop bound to the cationic rhenium clusters. For larger clusters \((n=10–13)\), bands also occur around 1800 cm\(^{-1}\); stronger depletions are observed when two CO molecules are bound. The separation of roughly 200 cm\(^{-1}\) from the signals assigned to atop bound CO is similar to that for the ruthenium clusters and indicates the bands arise from CO bridge bound to the cationic rhenium clusters. Additional signals are observed at even lower frequencies, around 1575 cm\(^{-1}\). Considering the shift of again about 200 cm\(^{-1}\) from the \(\nu(CO)\) of bridged bound species, these bands are probably due to \(\mu_3\)-CO bound to a hollow site on the cationic rhenium clusters. Similar hollow site binding has been previously observed for ionic palladium clusters.\(^10\)

D. Tungsten

The IR depletion spectra for neutral W\(_n\)CO \((n=5–14)\) are shown in Fig. 4. For W\(_n\)CO \((n=5,7–9,11)\), broad bands appear in the spectrum in the 1700–1950 cm\(^{-1}\) range. For \(n=5,9,\) and 11 these bands have a more pronounced minimum at ~1925 cm\(^{-1}\). To validate the character of these bands, additional experiments were performed with \(^{13}\)CO (red line in Fig. 4). Although it is not clear whether the broad absorption for W\(_7\)CO shifts with carbon-13 substitution, a redshift in the absorption bands according to the increase in the reduced mass is clearly present for the other cluster sizes.
We tentatively assign these bands at 1925 cm$^{-1}$ to CO atop bound to the clusters. Unfortunately, no direct comparison with CO on tungsten surfaces can be made, as here CO dissociates and only $\nu$(CO) values for carbon precovered surfaces have been determined (2040–2100 cm$^{-1}$).

In all of our investigations on CO adsorption to metal clusters, this is the first time that we have seen that the chemistry occurring on extended surfaces is clearly different from the chemistry occurring on small gas-phase clusters. For $W_n$CO, two absorption bands are present at 1665 and 1500 cm$^{-1}$. The one at 1665 cm$^{-1}$ is approximately 260 cm$^{-1}$ below the $\nu$(CO) assigned to atop bound CO, whereas the 1500 cm$^{-1}$ band is an additional 165 cm$^{-1}$ red-shifted. Although these separations are slightly different from the $\sim$200 cm$^{-1}$ shifts observed for the more coordinated CO on the ionic rhenium and rhenium clusters, they most likely are due to bridge bound and hollow site bound CO, respectively. For $W_{13}$CO and $W_n$CO ($n \geq 12$), no noticeable absorption bands are observed (note the different intensity scale for these sizes in Fig. 4). Although not a definitive proof, this indicates the general absence of molecular CO ligands due to the dissociation of carbon monoxide on these sized clusters. Hence, tungsten apparently shows size dependent nondissociative bonding of carbon monoxide on the clusters. Only for larger sized tungsten clusters does CO appear to dissociate. With respect to the CO binding behavior, bulklike properties already emerge for tungsten metal clusters containing more than 11 atoms. For extended tungsten surfaces, CO that is adsorbed initially at low temperature in a “virgin” molecular state is found to dissociate near room temperature.

Additional molecular ($\alpha$-CO) states are known to exist, but get only populated subsequent to saturation of the dissociative $\beta$-CO state.\(^{48,51}\) In our experiments, cooling the reaction channel from $\sim$300 to 100 K did not change the CO binding behavior on the clusters. Finally, it should be noted that carbon monoxide is found to completely dissociate on neutral clusters containing 4–20 atoms of tantalum, the element to the left of tungsten in the Periodic Table.

### E. Periodic trends

Figure 5 shows a plot of the assigned frequencies for CO adsorbed to these metal clusters as a function of cluster size. The values of $\nu$(CO) assigned to atop bound CO on the charged clusters gradually shift with increasing cluster size to lower frequencies for the cations and to higher frequencies for the anions. This is similar as observed before for other metals and can be related to the charge dilution effect.\(^{7}\) Here, however, this is superimposed by strong size-dependent fluctuations. To illustrate the trends in the C–O bond activation across the transition metals, the observed (averaged) $\nu$(CO) values assigned to atop bound CO on neutral metal clusters are plotted versus the group number in Fig. 6. The plot uses data reported here, but also from our previous experiments.\(^{7,12,14}\) For iron and tungsten the average of $\nu$(CO) of all neutral clusters is used, whereas for rhenium the average of $\nu$(CO) for the cationic and anionic species is taken as the average value for the neutral cluster.

The trends for $\nu$(CO) can be explained by the evolution of the electronic properties within the transition metals. For metal carbonyls, $\sigma$ bonding between the metal center and CO ligands is found to have no major influence of the C–O stretching frequency, but rather it is the $\pi$ back-bonding interaction which has a strong influence on $\nu$(CO).\(^{7,52}\) Moving to the left in the Periodic Table results in a rise of the metal Fermi energy level and of the diffuseness of the metal’s $d$

Electrons. This results in more $\pi$ back-bonding to the CO antibonding $2\sigma$ orbital, and the weakening of the C–O bond, until CO binds dissociatively.\(^\text{55}\) Consequently, the C–O stretching frequency for CO adsorbed on clusters of early transition metals are at lower frequencies than those of the later transition metal clusters. Similarly, the Fermi energy level becomes increasingly lower moving down a family, and the C–O stretching frequency increases successively when going from the 3$d$ metal to the heavier homologs.

**IV. CONCLUSION**

IR-MPD spectra of carbon monoxide adsorbed to clusters of iron, ruthenium, rhenium, and tungsten have been presented. It is found that CO binds molecularly in atop positions on neutral iron clusters. For ionic ruthenium clusters, CO also holds true, for the most part, for small clusters of metal surfaces would molecularly or dissociatively adsorb CO also holds true, for the most part, for small clusters of iron, ruthenium, rhenium, and tungsten clusters. The observed change in $\nu$(CO) allows a more quantitative description of the weakening of the C–O bonds and is largely in agreement with the trends on extended surfaces.
