Search for the decay $B^0_s \rightarrow \mu^+\mu^-$ with the ATLAS detector

The ATLAS Collaboration

Abstract

A blind analysis searching for the decay $B^0_s \rightarrow \mu^+\mu^-$ has been performed using proton-proton collisions at a centre-of-mass energy of 7 TeV recorded with the ATLAS detector at the LHC. With an integrated luminosity of 2.4 fb$^{-1}$ no excess of events over the background expectation is found and an upper limit is set on the branching fraction $\text{BR}(B^0_s \rightarrow \mu^+\mu^-) < 2.2(1.9) \times 10^{-8}$ at 95% (90%) confidence level.

Abstract

A blind analysis searching for the decay $B_s^0 \rightarrow \mu^+\mu^-$ has been performed using proton-proton collisions at a centre-of-mass energy of 7 TeV recorded with the ATLAS detector at the LHC. With an integrated luminosity of 2.4 fb$^{-1}$ no excess of events over the background expectation is found and an upper limit is set on the branching fraction $\text{BR}(B_s^0 \rightarrow \mu^+\mu^-) < 2.2(1.9) \times 10^{-8}$ at 95% (90%) confidence level.

Keywords: b-meson, rare decays, FCNC, ATLAS, LHC

1. Introduction

Flavour changing neutral current processes are highly suppressed in the Standard Model (SM), and therefore their study is of particular interest in the search for new physics. The SM predicts the branching fraction for the $B_s^0 \rightarrow \mu^+\mu^-$ to be extremely small: $(3.5 \pm 0.3) \times 10^{-9}$ \cite{1,2}. This process might be substantially enhanced by coupling to non-SM heavy particles, such as those predicted by the Minimal Supersymmetric Standard Model \cite{3,11} and other extensions \cite{12}. Upper limits on this branching fraction, in the range $(0.45-5.1) \times 10^{-8}$, have been reported by the D0 \cite{13}, CDF \cite{14}, CMS \cite{15,16} and LHCb \cite{17,18} collaborations. This Letter reports the result of a search performed with pp collisions corresponding to an integrated luminosity of 2.4 fb$^{-1}$, collected in the first half of the 2011 data-taking period using the ATLAS detector at the LHC.

The analysis is based on events selected with a di-muon trigger and reconstructed in the ATLAS inner tracking detector and muon spectrometer \cite{19}. Details of the detector, trigger and datasets are discussed in Section 2 together with the preselection criteria.

The $B_s^0 \rightarrow \mu^+\mu^-$ branching fraction is measured with respect to a prominent reference decay ($B^\pm \rightarrow J/\psi K^\pm$) in order to minimize systematic uncertainties in the evaluation of the efficiencies and acceptances, while still providing small statistical uncertainties. The branching fraction can be written as

$$\text{BR}(B_s^0 \rightarrow \mu^+\mu^-) = \text{BR}(B^\pm \rightarrow J/\psi K^\pm \rightarrow \mu^+\mu^- K^\pm) \times \frac{f_{B_s}}{f_{B^\pm}} \times \frac{N_{J/\psi K^\pm}}{N_{J/\psi K^\pm}} \times \frac{\epsilon_{J/\psi K^\pm}}{\epsilon_{J/\psi K^\pm}}$$ \text{SES} \times \text{SES}, \tag{1}

where the right-hand side includes the $B^\pm \rightarrow J/\psi K^\pm$ to $\mu^+\mu^- K^\pm$ branching fraction, the relative production probability of $B^\pm$ and $B_s$, and the corresponding limit on the branching fraction is presented in Section 4.

According to the SM, the branching fraction $\text{BR}(B_s^0 \rightarrow \mu^+\mu^-)$ is predicted to be about 30 times smaller than $\text{BR}(B_s^0 \rightarrow \mu^+\mu^-)$ \cite{1,2}. Therefore, despite the increased SES of approximately a factor four due to the absence of the factor $f_s/f_s$ and possible enhancements due to new physics, the sensitivity to this channel is beyond the reach of the current analysis. Hence only a limit on $\text{BR}(B_s^0 \rightarrow \mu^+\mu^-)$ was derived by assuming $\text{BR}(B_s^0 \rightarrow \mu^+\mu^-)$ to be negligible.

2. ATLAS detector, data and simulation samples

The ATLAS detector \cite{4} consists of three main components: an Inner Detector tracking system (ID) immersed...
in a 2 T magnetic field, a system of electromagnetic and hadronic calorimeters, and an outer Muon Spectrometer (MS). A full description can be found in [10]. The detector performance characteristics most relevant to this analysis are the vertex-finding and the overall track reconstruction in the ID and MS, together with the ability of the trigger system to record events containing pairs of muons.

The ID provides precise track reconstruction within the pseudorapidity range \(|\eta| < 2.5\). It employs a Pixel detector close to the beam-pipe, a silicon microstrip detector (SCT) at intermediate radii and a Transition Radiation Tracker (TRT) at outer radii. The innermost Pixel layer is located at a radius of 50.5 mm and plays a key role in precise vertex determination.

The MS comprises separate trigger and high-precision tracking chambers that measure the deflection of muons in a toroidal magnetic field. The precision chambers cover the region \(|\eta| < 2.7\) and measure the coordinate in the bending plane. The trigger chambers cover the range \(|\eta| < 2.4\) and provide fast coarser measurements in both the bending and non-bending plane. This analysis is based on a sample of \(pp\) collisions at \(\sqrt{s} = 7\) TeV, recorded by ATLAS in the period April–August 2011. Trigger and pile-up conditions changed for data taken after this period: the remainder of the 2011 dataset will be included in a future analysis. Data used in the analysis were recorded during stable LHC beam periods. Further data quality requirements were also imposed, notably on the performance of the MS and ID systems. The total integrated luminosity amounts to \(2.4\) fb\(^{-1}\). This sample has an average of about five primary vertices per event from multiple proton-proton interactions.

A muon trigger \([24]\) was used to select events. In particular, the sample contains events seeded by a Level-1 di-muon trigger which required a transverse momentum \(p_T > 4\) GeV for both muon candidates. A full track reconstruction of the muon candidates was performed at the second and third trigger levels, where additional cuts on the di-muon invariant mass \(m_{\mu^+\mu^-}\) were applied, loosely selecting events compatible with \(J/\psi (2500\) to \(4300\) MeV) or \(B^0\) (4000 to 8500 MeV) decays into a muon pair.

Events containing candidates for \(B^0\to \mu^+\mu^-\), \(B^\pm \to J/\psi K^{\pm}\) and \(K^+K^-\), as discussed in Sections 3.2 and 3.3, were required to have \(|\eta| < 2.5\) and \(p_T > 5\) GeV for muons (kaons). All reconstructed \(B^\pm\) candidates were required to satisfy \(m_\tau \geq 8.0\) GeV and \(|\eta^{\tau}| < 2.5\) in order to define our efficiencies and acceptances within a fiducial phase-space volume with as little as possible reliance on MC extrapolations. Signal and sideband regions were defined according to Table 1.

Table 1: Definition of the signal and sideband regions used in this analysis.

The primary vertex position was obtained from a fit of charged tracks not used in the decay vertex and constrained to the interaction region of the colliding beams. If multiple candidate primary vertices were present, the one closest in \(z\) to the decay vertex was chosen. After preselection, approximately \(2 \times 10^5\) \(B^0\to \mu^+\mu^-\) and \(1.4 \times 10^5\) \(B^\pm \to J/\psi K^{\pm}\) candidates were obtained in the signal regions.

Samples of Monte Carlo (MC) events were used for the extraction of acceptance and efficiency ratios. MC samples were produced for the signal channel \(B^0\to \mu^+\mu^-\), the reference channel \(B^\pm \to J/\psi K^{\pm}\) and the control channel \(B^0\to J/\psi \phi\). These samples were generated with PYTHIA 6.4 using the 2010 ATLAS \([24, 26]\) tune. MC events were filtered before detector simulation to ensure the presence of at least one decay of interest, with B decay products all satisfying \(|\eta| < 2.5\) and \(p_T > 2.5\) (0.5) GeV for muons (kaons). An additional sample was generated with a fictitious value of the \(B^0\) mass (6500 MeV) and the same parameters as the standard \(B^0\) sample, allowing a check of the full analysis on a signal-free region before unblinding. The ATLAS detector and its response were simulated using GEANT4 \([27]\). Additional \(pp\) interactions in the same and nearby bunch crossings (pile-up) were included in the simulation.

the \(x\)-axis points to the centre of the LHC ring and the \(y\)-axis points upward. Cylindrical coordinates \((r, \phi)\) are used in the transverse plane, \(\phi\) being the azimuthal angle around the beam pipe. The pseudorapidity \(\eta\) is defined as \(\eta = -\ln \tan(\theta/2)\) where \(\theta\) is the polar angle.
3. Event selection

This Section describes the expected background composition, the discriminating variables used as input to the multivariate classifier, the tuning of the simulation for the determination of the signal efficiency, the data samples used to estimate the background rejection and the optimization procedure. The signal efficiency was determined from MC samples, re-weighted to account for differences between data and MC simulation of the B meson kinematics. The rejection power was tested using a sub-sample of background events from the sidebands in the di-muon mass spectrum.

3.1. Background composition

Two categories of background were considered: a continuum with a smooth dependence on the di-muon invariant mass, and sources of resonant contributions from mis-reconstructed decays.

Comparisons of data and MC have shown that the combinatorial background from $b\bar{b} \rightarrow \mu^+\mu^-X$ decays provides a reasonable description for the distributions of the discriminating variables for the events found in the sidebands. The $b\bar{b} \rightarrow \mu^+\mu^-X$ MC sample used is equivalent to about 12 pb$^{-1}$ of integrated luminosity. Such studies support the procedure of modeling the continuum background through interpolation of the di-muon yield in the sidebands, but do not reach a sufficient statistical precision. Half of the data events in the sidebands (those with odd event numbers) were used to optimize the selection procedure. The remaining events were used for the measurement of the background and for interpolation to the signal region.

Resonant background is due to $B$ decay candidates containing either one or two hadrons erroneously identified as muons. Mis-identification may be due to punch-through of a hadron to the MS or to decays in flight where the muon carries most of the hadron momentum. In either case the hadron fakes the muon signature for the purpose of this analysis. Single-fake events are due to, e.g., $B_s^0 \rightarrow K^+\mu^-\nu$, the charged $K$ meson being mis-identified as a muon. Double-fake events are due to two-body hadronic $B$ decays ($B \rightarrow hh$), e.g., $B_{s}^{0} \rightarrow K^{+}\pi^{-}$, where both hadrons are mis-identified as muons. MC studies have shown that double-fake events are the main source of resonant background after the selection criteria used in this analysis. The main contribution is from $B_s^{0} \rightarrow K^{+}K^{-}$, followed by $B^{0} \rightarrow \pi^{+}\pi^{-}$ and $B^{0} \rightarrow K^{+}\pi^{-}$.

The simulation determined the probability for a hadron to be misidentified as a muon to be equal to 2 (4) % for $\pi^{\pm}$ ($K^{\pm}$), with a relative uncertainty of 20 %, validated against control samples in data. The value for charged $K$ mesons was averaged over $K^{+}$ and $K^{-}$ and was found consistent with the preliminary results of data-driven studies based on the decay $D^{\ast} \rightarrow D^{0}\pi^{\pm}$ to $K\pi\pi$.

The expected event yield for $B \rightarrow hh$ was obtained from an estimation of the integrated luminosity, acceptance and efficiency. This constitutes a nearly irreducible background in this analysis, due to its resemblance to the actual signal.

Table 2: List of the discriminating variables used in this analysis to separate $B_s^0 \rightarrow \mu^+\mu^-$ signal from backgrounds. These variables are based on properties of the decay products, of the reconstructed primary ($x_{PV}$) and secondary ($x_{SV}$) vertices (separated by $\Delta x = x_{SV} - x_{PV}$), the $B$ meson momentum $p_T$ and the properties of additional tracks from the underlying event. Variables are listed in order of relevance as ranked by the multivariate classifier used in the final signal/background separation as discussed in Section 3.4.2.

3.2. Discriminating variables

Table 2 describes the discriminating variables used in the multivariate classifier. The $B_s^0 \rightarrow \mu^+\mu^-$ signal is characterized by the separation between the production (primary) and decay (secondary) vertices, as well as the two-body decay topology. These variables exploit such features to discriminate against potential backgrounds: pairs of prompt charged tracks (e.g. $I_{x_{SV}}$, $ct$ significance, $\chi^2_{xy}$), as well as pairs of displaced muons originating from $b\bar{b} \rightarrow \mu^+\mu^- X$ processes (e.g. $d_0^{\text{max}}$, $d_0^{\text{min}}$), secondary vertices with additional particles in the final state (e.g. $\alpha_{2D}$, $\Delta R$, $D_{y_{SV}}^{\text{max}}$, $D_{y_{SV}}^{\text{min}}$) and non-$b\bar{b}$ processes (e.g. $I_0, I_7$, $p_T^B$, $p_T^L^{\text{max}}$, $p_T^L^{\text{min}}$).

Figure 1 shows how the discriminating variables are distributed for signal and background. Among the discriminating variables, isolation ($I_{0,7}$) is expected to have the largest pile-up dependence. In order to minimize this dependence, the definition of $I_{0,7}$ was restricted to only
Figure 1: Signal (filled histogram) and sideband (empty histogram) distributions for the selection variables described in Table 2. The $B_s^0 \rightarrow \mu^+\mu^-$ signal (normalized to the background histogram) is from simulation and the background is from data in the invariant-mass sidebands.
include tracks originating from the primary vertex associated with the $B$ decay. This specification makes the selec-

3.3. MC re-weighting and comparison to data

Monte Carlo samples were produced for the signal, reference and control channels, with specific requirements on the $B$ meson decay products as described above in Section 2. In order to ensure that the data are reproduced as closely as possible, the simulation was tuned by an iterative re-weighting procedure: a generator-level (GL) re-weighting based on simulation, followed by a data driven (DD) re-weighting.

For the GL re-weighting, additional MC samples were generated without selection on the final states and over a wider range in the $b$-quark kinematics: $|\eta^B| < 4$ and $p_T^B > 2.5$ GeV. These samples allowed a binned ($p_T^B, \eta^B$) map of the efficiencies of the generator-level selections to be derived for both the signal and the reference MC. The inverse of such efficiencies was then used to weight events individually, thus correcting the GL biases. These corrections were applied independently to the simulated reference and signal channel samples to correct for the biases in the relative $B^+_s/B^+$ acceptance induced by the generator-level selection. Possible residual biases were found to be negligible within the fiducial region $|\eta^B| < 2.5$ and $p_T^B > 8.0$ GeV.

Residual $(p_T^B, \eta^B)$ differences between data and MC were observed after GL reweighting. These were addressed with the DD re-weighting procedure, based on the comparison of MC events to the large sample of $B^\pm \to J/\psi K^\pm$ decays in collision data. In order not to correlate the re-weighting procedure with the yield measurement, only candidates with odd event numbers in the ATLAS dataset were used in this procedure, while the remaining sample was used for the yield measurement.

DD weights were determined by an iterative method, comparing re-weighted MC events with sideband-subtracted $B^\pm \to J/\psi K^\pm$ events in data. The procedure was applied separately to the $B$ meson variables $p_T^B$ and $\eta^B$ due to the limited number of reconstructed $B^\pm \to J/\psi K^\pm$ events in data, deriving the weights:

$$W_{ij}(p_T^B, \eta^B) = w_i(p_T^B) \times w_j(\eta^B)$$

where $W$ represents the final DD weights, the indices $i$ and $j$ refer to bins in $p_T^B$ and $\eta^B$, and $w_k = N_k^{data}/N_k^{MC}$ is the data-to-MC ratio of the normalized number of entries for each variable. The convergence and the consistency of the procedure, together with the factorization assumption of Eq. 3 were tested with additional MC samples, where intentionally distorted $(p_T^B, \eta^B)$ spectra were found to converge to the expected distributions. Effects related to the finite resolution in the measured variables were estimated to be smaller than 1% of the bin content and are therefore negligible when compared to statistical uncertainties.

Generator-level biases were addressed by applying the GL re-weighting before the DD re-weighting, and by verifying that this correction yields compatible $(p_T^B, \eta^B)$ spectra for $B^0_s \to \mu^+\mu^-$ and $B^\pm \to J/\psi K^\mp$ MC samples. Finally, the full re-weighting procedure was applied to $B^0_s \to J/\psi \phi$ decays, verifying within statistical uncertainty the consistency of the weights with those from $B^\pm \to J/\psi K^\pm$.

Distributions from $B^\pm \to J/\psi K^\pm$ in MC simulation and data were compared, after side-band background subtraction, for all discriminating variables listed in Table 2 and for variables used in the preselection. Agreement between MC and data was found for most of the variables. Figure 3 shows comparisons for $L_{xy}$ and $I_{0,7}$. Systematic effects associated with the residual data-MC differences are discussed in Section 4. The uncertainties on the GL×DD weights are dominated by systematic uncertainties obtained from the comparison between data and MC. They were propagated through the analysis and included among the systematic uncertainties in the signal extraction, as discussed in Section 4.
3.4. Selection optimization

The optimization of the event selection was performed by maximizing the estimator:

\[ \mathcal{P} = \frac{\epsilon_{\text{sig}}}{\frac{1}{2} + \sqrt{N_{\text{bkg}}}} \],

(4)

where \( \epsilon_{\text{sig}} = A_{\mu^+\mu^-} \epsilon_{\mu^+\mu^-} \) and \( N_{\text{bkg}} \) are the signal acceptance times efficiency relative to the simulated phase space of the samples in section 3.3 (corresponding to the signal efficiency defined for \( |\eta|^{B^\pm} < 2.5 \) and \( p_T^{B^\pm} > 8.0 \) GeV) and the background yield for a given set of cuts. The extraction of \( N_{\text{bkg}} \) is performed by sideband interpolation as described in section 3.3. The coefficient \( a \) was determined by the confidence level (CL) sought in the analysis, with \( a=2 \) for a 95% CL limit. This quantity is specifically designed to optimize the performance of a frequentist limit determination in a counting analysis [30].

First, a simplified optimization procedure was performed on a small set of variables that includes: \( |a_{2D}| \), \( I_{0.7} \), \( ct \), and width \( \pm \Delta m \) of the search window centred around the \( B^0 \) mass (rounded to 5366 MeV). A four-dimensional scan was performed on the four variables, using odd-numbered events in the sidebands. The optimal selection cuts are shown in Table 3 where the signal efficiency \( A_{\mu^+\mu^-} \epsilon_{\mu^+\mu^-} \), the background estimated from sidebands interpolation and the value of \( \mathcal{P} \) are also given. This selection serves as a benchmark for the optimization of the multivariate analysis described in Section 3.4.2.

| \( |a_{2D}| \) | \( ct \) | \( I_{0.7} \) | \( \Delta m \) | \( \epsilon_{\text{sig}} \) | \( N_{\text{bkg}} \) | \( \mathcal{P} \) |
|---|---|---|---|---|---|---|
| <0.03 | >0.3 mm | >0.83 | \( \pm 105 \) MeV | 0.040 | 9\pm2 | 0.010 |

Table 3: Optimal selection variable cuts for the four-variables scan, and resulting analysis performance in terms of signal acceptance times efficiency \( (\epsilon_{\text{sig}}) \), background yield in the signal region \( (N_{\text{bkg}}) \) and the estimator \( \mathcal{P} \).

3.4.1. Categories of invariant-mass resolution

The ability to resolve a small \( B^0 \rightarrow \mu^+\mu^- \) signal from the continuum background depends on the width \( \Delta m \) of the search region and is therefore affected by the resolution. The latter varies considerably over different sub-samples of muon pairs measured by ATLAS, due to the increase in multiple scattering and the decrease of the magnetic field integral at large values of \( |\eta| \). The non-resonant background invariant mass distribution was observed to be relatively independent of \( \eta \). As a consequence, different mass-resolution categories correspond to different signal-to-background conditions.

In the statistical analysis, regions of different mass resolution and hence signal-to-background ratio were separated in order to optimize them independently. The sample was separated into three categories, defined by the larger pseudorapidity value \( |\eta_{\text{max}}| \) of the two muons in each event. The three categories were defined by the intervals \( |\eta_{\text{max}}| = 0–1, 1–1.5 \) and \( 1.5–2.5 \). The corresponding average values of the mass resolution are approximately 60, 80 and 110 MeV, respectively. The relative population of each interval, in \( B^0 \rightarrow \mu^+\mu^- \) signal MC, amounts to 51%, 24% and 25%.

The same classification, based on \( |\eta_{\text{max}}| \), was used for the reference channel \( B^\pm \rightarrow J/\psi K^\pm \), and separate values of the acceptance-times-efficiency ratio were obtained for each category, as discussed in Section 4.1.

3.4.2. Multivariate selection

The selection with optimal cuts was used to validate the multivariate analysis tool used for the final results. The TMVA package [31] implementation of Boosted Decision Trees (BDT) was found to have the best performance and was selected for this analysis. As a first step, it was verified that for fixed values of \( \Delta m \), the optimal BDT corresponds to selections in the variables \( a_{2D} \), \( ct \) and \( I_{0.7} \) directly comparable to those obtained with the cuts shown in Table 3. Next, the discriminating variables of Table 2 were introduced one-by-one into the BDT, verifying that the multivariate optimization increased the signal efficiency and the value of \( \mathcal{P} \). With the BDT approach
the $P$ estimator improved from $P = 0.010$ found in the simplified optimization to $P = 0.016$.

In order to avoid biases in the background interpolation, the BDT selection should be insensitive to the mass of the muon pair. The BDT inputs have no correlation with the invariant mass. Residual correlations in the BDT output were studied through the search for a fictitious decay $X \rightarrow \mu^+\mu^-$ with $m_X = 6500$ MeV. A Monte Carlo sample was used to provide reference signal events, while data in the mass intervals 5900 to 6200 MeV and 6800 to 7000 MeV were used as background. The BDT training and selection optimization were consistently performed on odd-numbered events. Figure 4 shows the BDT output as a function of the di-muon mass, over the sideband regions and the fictitious signal region (6200 to 6800 MeV), which was not used in the optimization. No significant mass dependence was observed.

The optimization of the multivariate analysis was performed in the six-dimensional space of $\Delta m$ and the BDT output cuts for each of the mass-resolution categories. The independence of the BDT output on $m_{\mu^+\mu^-}$ and the complementarity of the samples allow the factorization of the individual cut efficiencies. Each efficiency curve was interpolated with analytical models, allowing the numerical maximization of $P$ and yielding the optimal cuts reported in Table 4.

### 4. Single Event Sensitivity ingredients

#### 4.1. Relative acceptance and efficiency

The ratio of the acceptance times efficiency products for the charged and neutral decays

$$R_Ac = (A_{J/\psi K} \epsilon_{J/\psi K})/(A_{\mu^+\mu^-} \epsilon_{\mu^+\mu^-})$$

is required for the determination of the SES (Eq. 1). The same BDT, trained on the $B^0_s \rightarrow \mu^+\mu^-$ signal MC sample and di-muon data sidebands, was used to select both decay modes.

The uncertainty on $R_Ac$ is affected by differences between data and MC in the distributions of the discriminating variables. Such differences are reduced by the data-driven corrections applied to the MC $B$-meson kinematics. Furthermore, only deviations that act incoherently between the signal and the reference channel contribute to the uncertainty on $R_Ac$. These effects were studied by observing the change in the relative efficiency of the BDT selection when the simulated events were re-weighted by the data-to-MC ratio of the distributions of the most sensitive variables in $B^{\pm} \rightarrow J/\psi K^{\pm}$ events. The procedure was performed with the cut on the BDT output fixed at the optimal value for each of the three event categories. Conservatively, the corresponding variations in $R_Ac$ were combined linearly and taken as systematic uncertainties.

Due to large correlations between $L_{xy}$, $\chi^2_{xy}$ and $c$-significance, correcting for the differences in $L_{xy}$ between data and simulation was found to also effectively remove differences in the other two variables. Therefore only $L_{xy}$ was considered, since it induced the largest deviation in $R_Ac$. Differences in the $\eta$ and $p_T$ distributions of the final state particles, the hit multiplicity in the Pixel detector, and the multiplicity of reconstructed primary vertices were included in the systematic uncertainty evaluation.

Figure 5 shows the distribution of the BDT output for MC samples of $B^0_s \rightarrow \mu^+\mu^-$ and $B^\pm \rightarrow J/\psi K^{\pm}$ decays, with a signal–background comparison for $B^0_s \rightarrow \mu^+\mu^-$ and a sideband-subtracted data–MC comparison for $B^{\pm} \rightarrow J/\psi K^{\pm}$. As shown in Table 4, the selection required the BDT output to exceed 0.23–0.27, depending on the mass-resolution category. The systematic uncertainties induce a fractional change in the number of events passing the BDT cut varying between 10% and 20% depending on the category. This change is highly correlated between the two channels: the corresponding variation on the efficiency ratio is 0.6%, which was taken as a systematic uncertainty and is smaller than the $\pm 2.3\%$ error due to the finite MC statistics.

The value of $R_Ac$ and its systematic uncertainties (shown in Table 5) were derived separately in the three mass-resolution categories. The MC-based efficiency was compared with that from $B^\pm \rightarrow J/\psi K^{\pm}$ data, computing the efficiency of the BDT cut relative to the preselection. The results are of similar precision and fully consistent: $0.258 \pm 0.013$ (stat) for the data and $0.234 \pm 0.014$ (stat) ±

5. Inputs to the limit extraction

The evaluation of the SES requires as input the combined branching fraction for the reference channel $B^\pm \to J/\psi K^\pm \to \mu^+\mu^- K^\pm$, which is $(6.01 \pm 0.21) \times 10^{-5}$ [20]. The relative production rate of $B^0_s$ relative to $B^\pm$ $f_s/f_u$ is $0.267 \pm 0.021$ [22], assuming $f_u = f_d$ (following Ref. [21]) and no kinematic dependence of $f_s/f_u$. The ratio of acceptance-times-efficiency is discussed in Section 3.3 and presented in Table 5. The branching fractions uncertainties, those on $f_s/f_u$, together with those mentioned in the last paragraph of Section 4.1 were treated coherently in the three categories of mass resolution.

4.2. $B^\pm \to J/\psi K^\pm$ event yield

The reference channel yield $N_{J/\psi K^\pm}$ was determined from a binned likelihood fit to the invariant mass distribution of the $\mu^+\mu^- K^\pm$ system, performed in the mass range 4930–5630 MeV. To avoid any bias induced by the DD re-weighting of the MC samples discussed in Section 4.3 only even-numbered events were used in the extraction of the $B^\pm \to J/\psi K^\pm$ event yield. The $B^\pm$ signal was modelled with two Gaussian distributions of equal mean value. The background was modelled with the sum of: (a) an exponential function for the continuum combinatorial background; (b) an exponential function multiplied by a complementary error function describing the low-mass ($m < 5200$ MeV) contribution for partially reconstructed decays (such as $B \to J/\psi K^*$, $B \to J/\psi K(1270)$ and $B \to \chi_c K$); and (c) a Gaussian function for the background from $B^\pm \to J/\psi \pi^\pm$. Figure 6 shows the invariant mass distribution and the result of the fit for the selected data sample.

All parameters describing the signal and background were determined from the fit, with the exception of the mass and the width of the last component (c), which were obtained from simulation. The fit was performed for each of the three categories of mass resolution.

Systematic uncertainties affecting the extracted reference yield were estimated by varying the fit model: use of different bin sizes (10 or 25 MeV and unbinned), different models for signal and continuum background, inclusion of event-wise di-muon mass resolution. The resulting $B^\pm$ yields are given with their statistical and systematic uncertainties in Table 6.

| $|\eta|_{\text{max}}$ | Range          | 0–1.0 | 1.0–1.5 | 1.5–2.5 |
|-------------------|-----------------|------|---------|---------|
| $B^\pm \to J/\psi K^\pm \to \mu^+\mu^- K^\pm$ | statistical uncertainty | ±1.6% | ±2.8%  | ±3.0%  |
| systematic uncertainty | ±2.9% | ±7.4%  | ±14.1% |

Table 6: Event yield for even-numbered candidates in the reference channel.
as found after unblinding. Figure 6 shows the invariant mass distribution of the selected candidates in data, for the three mass categories, together with the signal projections as obtained from MC assuming $\text{BR}(B^0 \rightarrow \mu^+\mu^-) = 3.5 \cdot 10^{-8}$ (i.e. approximately 10 times the SM expectation).

In each mass-resolution category the $B^0 \rightarrow \mu^+\mu^-$ signal yield $N_{\mu^+\mu^-}$ was obtained from the number of events observed in the search window, the number of background events in the sidebands, and the small amount of resonant background discussed in Section 3.1. The expected ratio of the background events in the sidebands to those in the search window is described by the parameter $R_{i}^{\text{bkg}}$, which depends on the width of the invariant-mass interval and on the fraction of events from the sidebands used for the interpolation. The former varies according to the mass-resolution category, and the latter is equal to 50%, corresponding to the even-numbered events in the data collection. Uncertainties in the mass dependence of the continuum background produced a ±4% systematic error in the value of $R_{i}^{\text{bkg}}$, evaluated by studying the variation of $R_{i}^{\text{bkg}}$ for different BDT output cuts and background interpolation models. The systematic variation accounts also for additional background components in the low mass sidebands (e.g. partially reconstructed B decays). This uncertainty was treated coherently in the three mass-resolution categories.

The values of the SES are given in Table 7 which also shows the values of the parameters $R_{i}^{\text{bkg}}$, the background counts in the sideband, the resonant background, and finally the observed number of events in the search region.

2For comparison, the number of odd-numbered events observed in the sidebands, which is expected to be biased due to the use of the same sample in selection optimization and BDT training, was found to be equal to one event in each of the three mass-resolution categories.
6. Branching fraction limits

The upper limit on the $B_s^0 \rightarrow \mu^+\mu^-$ branching fraction was obtained by means of an implementation [32] of the CLs method [23]. The extraction was based on the likelihood:

\[
\mathcal{L} = \text{Gauss}(\epsilon_{\text{obs}}, \sigma_\epsilon) \times \text{Gauss}(R_{\text{obs}}^{\text{bkg}}, \sigma_{R_{\text{obs}}^{\text{bkg}}}) \times \prod_{i=1}^{N_{\text{bin}}} \text{Poisson}(N_{\text{obs}}^{i\text{bkg}} | \epsilon_i \mu \rightarrow \mu \mu + N_i^{B \rightarrow hh} + N_i^{B \rightarrow hh} \times \mu \rightarrow \mu \mu) \times \text{Gauss}(\epsilon_{\text{obs}}, \sigma_\epsilon).
\]

For each mass-resolution category, the likelihood contains Poisson distributions for the event counts in the search and sideband regions and a Gaussian distribution for the relative efficiency $\epsilon_i$. Two additional Gaussians describe the coherent systematic uncertainties in $R_i^{\text{bkg}}$ and in the SES. The mean of the Poisson distribution in the search region is equal to the sum of the $B_s^0$ branching fraction (scaled by the normalization and relative efficiency parameters), the continuum background and the resonant background. The mean of the Poisson distribution in the sidebands is equal to the background scaled by $R_i^{\text{bkg}}$. The parameters $\sigma_\epsilon (\epsilon_\epsilon), \sigma_{R_{\text{obs}}^{\text{bkg}}} (\sigma_{R_{\text{obs}}^{\text{bkg}}})$ account for the correlated (uncorrelated) uncertainties in the SES and the background scaling factor. In this analysis the uncertainties on $R_i^{\text{bkg}}$ are negligible, with $R_i^{\text{bkg}} = 1.00 \pm 0.04$. All input parameters are summarized in Table 7.

The expected limits were obtained by setting the counts in the search region equal to the interpolated background plus the small resonant background, before the unbiasing of the signal region. A median expected limit of $2.3^{+1.0}_{-0.5} \times 10^{-8}$ at 95% CL was obtained, where the range encloses 68% of the background-only pseudo-experiments.

For comparison the mass-resolution categories were merged and the selection optimization was performed on the merged sample. In this case eight events were found in the sidebands, resulting in a branching fraction limit of $2.9^{+1.3}_{-0.8} \times 10^{-8}$ at 95% CL. This test confirms the expectation of a more sensitive analysis when separate mass-resolution categories are used.

The background counts found in odd-numbered events were used to assess the magnitude of the bias that would be caused by using the same sample for selection optimization and the estimation of $N_i^{\text{bkg}}$. The expected limit obtained using the same sample for optimization and signal extraction is $1.7 \times 10^{-8}$, about 30% smaller than the limit presented in this Letter, for which independent samples were used for optimization and for signal extraction. The observed bias is consistent with simulation-based assessments of this effect.

Figure 8 shows the behaviour of the observed $\chi^2$ for different tested values of the $B_s^0 \rightarrow \mu^+\mu^-$ branching fraction, computed with 300 000 toy MC simulations per point. The observed limit is $< 2.2 (1.9) \times 10^{-8}$ at 95% (90%) CL. The $p$-values for the background-only hypothesis and for background plus SM prediction [1, 2] are 44% and 35%, respectively.

![Figure 8: Observed CLs (circles) as a function of BR($B_s^0 \rightarrow \mu^+\mu^-$). The 95% CL limit is indicated by the horizontal (red) line. The dark (green) and light (yellow) bands correspond to $\pm 1\sigma$ and $\pm 2\sigma$ fluctuations on the expectation (dashed line), based on the number of observed events in the signal and sideband regions.](image)

Table 7: Single event sensitivity and event counts in the three mass resolution categories. The second and third lines report how the SES= $(\epsilon_\epsilon)^{−1}$ was split between a coefficient common to all bins, and the per-bin component. The Table does not include the additional common uncertainties corresponding the sources mentioned in the last paragraph of Section 4.1 ($\pm 5.5%$ in $R_i^{\text{bkg}}$) and to the parameterization of the mass dependence of the continuum background ($\pm 4%$ in $R_i^{\text{bkg}}$).

| $|y|_{\text{max}}$ Range | 0–1.0 | 1.0–1.5 | 1.5–2.5 |
|-------------------------|-------|---------|---------|
| SES= $(\epsilon_\epsilon)^{−1}$ [10^{-8}] | 0.71 | 1.6 | 1.4 |
| $\epsilon = (f_s/f_u)/\text{BR}(B_s^0 \rightarrow J/\psi K^0 \rightarrow \mu^+\mu^- K^\pm)$ [10^3] | 4.45 \pm 0.38 |
| $\epsilon_i = N_i^{B \rightarrow hh} / R_i^{\text{bkg}}$ [10^2] | 3.14 \pm 0.17 | 1.40 \pm 0.15 | 1.58 \pm 0.26 |
| bkg. scaling factor $R_i^{\text{bkg}}$ | 1.29 | 1.14 | 0.88 |
| sideband count $N_{\text{obs}}^{\text{bkg}}$ (even numbered events) | 5 | 0 | 2 |
| expected resonant bkg. $N_i^{B \rightarrow hh}$ | 0.10 | 0.06 | 0.08 |
| search region count $N_{\text{obs}}^{\text{bkg}}$ | 2 | 1 | 0 |
Despite the difference between the total numbers of observed and interpolated background events (equal to 3 and 6.5, respectively), the interplay of the event counts observed in the three mass resolution categories produced an observed CL$_{S}$ limit close to the expected value.

7. Conclusions

A limit on the branching fraction $\text{BR}(B_{s}^{0} \rightarrow \mu^{+}\mu^{-})$ is set using 2.4 fb$^{-1}$ of integrated luminosity collected in 2011 by the ATLAS detector. The process $B_{s}^{+} \rightarrow J/\psi K_{s}^{0}$, with $J/\psi \rightarrow \mu^{+}\mu^{-}$, is used as a reference channel for the normalization of integrated luminosity, acceptance and efficiency. The final selection is based on a multivariate analysis performed on three categories of events determined according to their mass resolution, yielding a limit of $\text{BR}(B_{s}^{0} \rightarrow \mu^{+}\mu^{-}) < 2.2 (1.9) \times 10^{-8}$ at 95% (90%) CL.

8. Acknowledgements

We thank CERN for the very successful operation of the LHC, as well as the support staff from our institutions without whom ATLAS could not be operated efficiently.

We acknowledge the support of ANPCyT, Argentina; YerPhI, Armenia; ARC, Australia; BMWF, Austria; ANAS, Azerbaijan; STSC, Belarus; CNPq and FAPESP, Brazil; NSERC, NRC and CFI, Canada; CERN; CONICYT, Chile; CAS, MOST and NSFC, China; COLCIENCIAS, Colombia; MSMST CR, MPO CR and VSC CR, Czech Republic; DNF, DNSRC and Lundbeck Foundation, Denmark; EPLANET and ERC, European Union; IN2P3-CNRS, CEA-DSM/IRFU, France; GANAS, Georgia; BMBF, DFG, HGF, MPG and AvH Foundation, Germany; GSRT, Greece; ISF, MINERA, GIF, DIP and Benoziyo Center, Israel; INFN, Italy; MEXT and JSPS, Japan; CNRST, Morocco; FOM and NWO, Netherlands; RCN, Norway; MNISW, Poland; GRICES and FCT, Portugal; MERSYS (MECTS), Romania; MES of Russia and ROSATOM, Russian Federation; JINR; MSTD, Serbia; MSSR, Slovakia; ARRS and MVZT, Slovenia; DST/NRF, South Africa; MICINN, Spain; SRC and Wallenberg Foundation, Sweden; SER, SNSF and Cantons of Bern and Geneva, Switzerland; NSC, Taiwan; TAEK, Turkey; STFC, the Royal Society and Leverhulme Trust, United Kingdom; DOE and NSF, United States of America.

The crucial computing support from all WLCG partners is acknowledged gratefully, in particular from CERN and the ATLAS Tier-1 facilities at TRIUMF (Canada), NDGF (Denmark, Norway, Sweden), CC-IN2P3 (France), KIT/GridKA (Germany), INFN-CNAF (Italy), NL-T1 (Netherlands), PIC (Spain), ASGC (Taiwan), RAL (UK) and BNL (USA) and in the Tier-2 facilities worldwide.
