Lipid overload and adipocyte dysfunction are key to the development of insulin resistance and can be induced by a high-fat diet. CD1d-restricted invariant natural killer T (iNKT) cells have been proposed as mediators between lipid overload and insulin resistance, but recent studies found decreased iNKT cell numbers and marginal effects of iNKT cell depletion on insulin resistance under high-fat diet conditions. Here, we focused on the role of iNKT cells under normal conditions. We showed that iNKT cell–deficient mice on a low-fat diet, considered a normal diet for mice, displayed a distinctive insulin resistance phenotype without overt adipose tissue inflammation. Insulin resistance was characterized by adipocyte dysfunction, including adipocyte hypertrophy, increased leptin, and decreased adiponectin levels. The lack of liver abnormalities in CD1d-null mice together with the enrichment of CD1d-restricted iNKT cells in both mouse and human adipose tissue indicated a specific role for adipose tissue–resident iNKT cells in the development of insulin resistance. Strikingly, iNKT cell function was directly modulated by adipocytes, which acted as lipid antigen-presenting cells in a CD1d-mediated fashion. Based on these findings, we propose that, especially under low-fat diet conditions, adipose tissue–resident iNKT cells maintain healthy adipose tissue through direct interplay with adipocytes and prevent insulin resistance.

Introduction

More than one-third of the U.S. population has insulin resistance, a condition that is predominantly caused by obesity and is associated with adipocyte dysfunction together with chronic low-grade adipose tissue (AT) inflammation (1–3). Lipid-induced adipocyte dysfunction appears instrumental to the inflammatory response in AT (4), which is characterized by inflammasome activation (5) and the release of fatty acids and cytokines (adipokines) that impair insulin receptor signaling, ultimately resulting in the development of metabolic syndrome (6–8).

Distinct mechanisms impart control of immune homeostasis within AT, some of which were recently uncovered. AT-resident Tregs together with eosinophils control the development of local inflammation by counteracting the influx of CD11c+ (M1) inflammatory macrophages, CD8+ T cells, CD4+ T cells, and B cells, thereby preventing AT inflammation and insulin resistance (9–16). How adipocyte dysfunction relates to immune homeostasis, however, remains incompletely understood, and a self-reactive cell type involved in orchestrating immune homeostasis in AT has not yet been reported. Various findings prompted us to study the role of lipid antigen–reactive invariant natural killer T cells (iNKT) cells in controlling AT inflammation and insulin resistance. First, the abundance of lipid antigens in AT preeminently suits lipid-sensitive invariant T cells such as iNKT cells, as they are triggered to release immune-polarizing cytokines by lipid/CD1d complex binding (17–19). Second, CD1d-restricted iNKT cells have roles in multiple metabolic disease models, including type 1 diabetes mellitus (20–23). Third, many tissues harbor resident T cells that can respond to stress-induced self molecules rather than foreign antigens and ensure a tissue-specific effector class (Th1, Th2, or tolerogenic) response (24). In AT, iNKT cells are known to fulfill this role in the liver, representing up to 40% of liver-resident T cells in mice (19). Fourth, we were intrigued by the apparent enrichment of iNKT cells in mouse and human AT compared with peripheral blood (our unpublished observations and refs. 25, 26), especially in lean mice and humans. Fifth, recent studies showed that under high-fat diet (HFD) conditions, CD1d-restricted iNKT cell function only marginally affects the development of insulin resistance (26–28). Accordingly, we hypothesized that AT-resident CD1d-restricted iNKT cell function may be particularly relevant under normal diet conditions.

We employed CD1d-null and Jx18-null mice, antibody depletion of iNKT cells in WT mice, and human AT to address the role of AT-resident CD1d-restricted iNKT cells. Our mouse-based data show a unique role for CD1d-restricted iNKT cells in the maintenance of healthy adipocytes and prevention of insulin resistance, especially under low-fat diet (LFD) conditions, considered a normal diet for mice (29). Furthermore, coculture of human CD1d-restricted iNKT cells with adipocytes revealed a potential mechanism linking adipocyte dysfunction to immune

cell homeostasis, showing that CD1d-proficient adipocytes can function as lipid APCs for iNKT cells.

**Results**

**iNKT cell knockout and antibody-mediated depletion result in insulin resistance in lean mice.** We addressed the impact of CD1d-restricted iNKT cells on AT homeostasis and insulin resistance using CD1d-null (30) and WT C57BL/6 mice. The mice were fed normal chow until 11 weeks of age, followed by 19 weeks of LFD or HFD. Weight gain, caloric intake, and epididymal fat pad weight were similar among the genotypes, for both LFD and HFD mouse groups (Figure 1, A–C). Strikingly, glucose tolerance measured via an intraperitoneal glucose tolerance test (IP-GTT) was clearly impaired in the CD1d-null mice compared with their WT counterparts, especially under LFD conditions (Figure 1, D–G). Under HFD conditions, CD1d-null mice showed higher insulin levels during the IP-GTT than their WT counterparts, but maintained comparable glucose levels (Figure 1, D–G), in accordance with previous studies (26–28). To corroborate these findings, we used Jct18-null mice, which are selectively deficient in type 1 iNKT cells (31). These animals also showed impaired glucose tolerance after 18 weeks of LFD compared with their WT counterparts (Figure 1, H and I) while maintaining comparable body weight (data not shown).

The insulin resistance in lean CD1d-null and Jct18-null mice was confirmed using an established iNKT depletion model, comparing antibody-treated (anti-NK1.1) with isotype control–treated LFD-fed WT mice (32, 33). Partial depletion of AT-resident iNKT cells resulted in impaired glucose tolerance compared with isotype control treatment (Figure 1, J and K, and Supplemental Figure 1A; supplemental material available online with this article; doi:10.1172/JCI62739DS1). When a gain-of-function approach was pursued by in vivo activation of iNKT cells in WT mice on LFD through injection of the CD1d-restricted iNKT cell ligand α-galactosyl ceramide (αGalCer), glucose tolerance did not improve (Supplemental Figure 2C and ref. 26), probably due to the fact that WT animals are highly insulin sensitive under LFD conditions. Taken together, these findings indicate that CD1d-restricted iNKT cells protect against insulin resistance, especially in LFD-fed mice.

As iNKT cells reside not only in AT (Figure 2) but also in the liver, and both organs are critically involved in the regulation of whole-body lipid and glucose homeostasis (34), we investigated circulating lipids and liver function in CD1d-null mice, focusing on whole-body lipid and glucose homeostasis (34), we investigated circulating lipids and liver function in CD1d-null mice, focusing on whole-body lipid and glucose homeostasis. For both LFD and HFD mouse groups (Figure 1, A–C). Strikingly, glucose tolerance measured via an intraperitoneal glucose tolerance test (IP-GTT) was clearly impaired in the CD1d-null mice compared with their WT counterparts, especially under LFD conditions (Figure 1, D–G). Under HFD conditions, CD1d-null mice showed higher insulin levels during the IP-GTT than their WT counterparts, but maintained comparable glucose levels (Figure 1, D–G), in accordance with previous studies (26–28). To corroborate these findings, we used Jct18-null mice, which are selectively deficient in type 1 iNKT cells (31). These animals also showed impaired glucose tolerance after 18 weeks of LFD compared with their WT counterparts (Figure 1, H and I) while maintaining comparable body weight (data not shown).

The insulin resistance in lean CD1d-null and Jct18-null mice was confirmed using an established iNKT depletion model, comparing antibody-treated (anti-NK1.1) with isotype control–treated LFD-fed WT mice (32, 33). Partial depletion of AT-resident iNKT cells resulted in impaired glucose tolerance compared with isotype control treatment (Figure 1, J and K, and Supplemental Figure 1A; supplemental material available online with this article; doi:10.1172/JCI62739DS1). When a gain-of-function approach was pursued by in vivo activation of iNKT cells in WT mice on LFD through injection of the CD1d-restricted iNKT cell ligand α-galactosyl ceramide (αGalCer), glucose tolerance did not improve (Supplemental Figure 2C and ref. 26), probably due to the fact that WT animals are highly insulin sensitive under LFD conditions. Taken together, these findings indicate that CD1d-restricted iNKT cells protect against insulin resistance, especially in LFD-fed mice.

As iNKT cells reside not only in AT (Figure 2) but also in the liver, and both organs are critically involved in the regulation of whole-body lipid and glucose homeostasis (34), we investigated circulating lipids and liver function in CD1d-null mice, focusing on LFD conditions. While circulating triglycerides were slightly elevated in CD1d-null mice on a LFD, circulating FFA and cholesterol levels were not (Supplemental Figure 1, B–D). More importantly, CD1d-null mice on a LFD showed none of the pathological alterations that are associated with liver-mediated insulin resistance (35): neither liver histology, weight, and lipid content nor the liver enzymes aspartate aminotransferase (AST) and alanine aminotransferase (ALT) and the liver inflammatory markers lipocalin-2 (Lcn2) and serum amyloid A (Saa2) were altered in CD1d-null mice on a LFD, compared with their WT counterparts (Supplemental Figure 1, E–K). In WT and CD1d-null mice under HFD conditions, though, liver pathology was observed; for some parameters, this was most pronounced in CD1d-null mice (Supplemental Figure 1, E–K). These findings argue against a principal role for the liver in the insulin-resistant phenotype observed in LFD-fed CD1d-null and iNKT cell–depleted mice. We therefore focused on the role of AT-resident iNKT cells.

AT-resident iNKT cells show an antinflammatory phenotype and are downregulated on a long-term HFD. AT-resident iNKT cells constitute 5%–10% of the visceral AT-resident (VAT-resident) T lymphocyte pool, as indicated by αGalCer-loaded CD1d tetramer and TCR β staining (Figure 2A). Compared with spleen-derived iNKT cells, which are predominantly CD4+ and clearly express NK1.1, AT-resident iNKT cells exhibit a phenotype biased toward CD4/CD8 double-negative (~70%) with reduced NK1.1 expression (~50%) (Figure 2, A, D, and E). Next, AT-resident iNKT cell cytokine production was analyzed. AT-resident iNKT cells showed an antinflammatory phenotype with high levels of intracellular IL-4 and IL-13 and lower levels of IFN-γ compared with splenic iNKT cells (Figure 2B). Production of all 3 cytokines was increased upon in vivo treatment with αGalCer, both in AT and splenic iNKT cells (Figure 2B). Functionality of AT-resident iNKT cells (i.e., cytokine production) was confirmed by ex vivo stimulation experiments (Supplemental Figure 2B). To address the contribution of iNKT cells to cytokine production in AT, we performed quantitative RT-PCR analysis on AT from WT and CD1d-null mice. A decrease in Il4 and Il13 mRNA levels in particular was observed in CD1d-null mice, indicating that iNKT cells contribute to the presence of these cytokines in AT (Figure 2C). We noticed a decrease in iNKT numbers in VAT and in subcutaneous AT (SCAT) in WT mice fed a HFD compared with a LFD (Figure 2F), which was not due to TCRβ downregulation (data not shown). In addition, reduced expression of signaling lymphocytic activation molecule f1 (SLAMf1) (36, 37) on the remaining iNKT cells was observed (Supplemental Figure 2A). Thus, low iNKT cell numbers and activity under HFD conditions may partly explain the relatively small differences in glucose tolerance observed between WT and CD1d-null mice on a long-term HFD.

**CD1d-null mice exhibit enhanced AT Treg numbers, preventing worsening of insulin resistance.** We next asked whether iNKT cells prevent the insulin resistance in CD1d-null mice on a LFD through an immune-modulatory mechanism, as shown in other tissues (17–19). Under HFD conditions, AT infiltration of CD8+ T cells, followed by infiltration of macrophages that exhibit an M1-polarized phenotype, plays a pivotal role in the development of insulin resistance (13, 38). However, CD1d-null mice on a LFD exhibited neither AT CD8+ T cell infiltration nor increased macrophage numbers and M1 polarization (Figure 3, A and B, and Supplemental Figure 3A). Only under HFD conditions did we observe increased macrophage numbers and M1 polarization in CD1d-null mice compared with their WT counterparts (Supplemental Figure 3, A and B). Instead, higher CD4+CD25+ CD8- T cell numbers were detected in AT of CD1d-null mice, on both LFD and HFD (Figure 3C and Supplemental Figure 3B). CD4+CD25+ CD8- T cells extracted from AT expressed high levels of Foxp3 (Figure 3D), and the number of CD4+Foxp3+ T cells (but not their MFI) was increased in the iNKT cell–depleted mice (Figure 3E and data not shown). Thus, complete absence of iNKT cells in CD1d-null mice and antibody-mediated iNKT cell depletion both result in an enrichment of Tregs in AT. Considering the protective role of Tregs in AT (9), we next addressed whether the increased Treg numbers prevent worsening of the insulin resistance phenotype. Upon anti-CD25 antibody–mediated depletion of Tregs in the CD1d-null mice on a LFD, an aggravation of the insulin-resistant phenotype observed in CD1d-null mice was seen (Figure 3, F and G, and Supplemental Figure 3C). Pointing to the importance of iNKT cells for this effect, depletion...
Figure 1
iNKT cell knockout and antibody-mediated depletion result in insulin resistance in lean mice. For A–H, n = 10 mice per group; total 40 mice. (A) Weight gain of WT and CD1d-null mice on the LFD and HFD regimens. Mice were weighed weekly. (B) Weekly caloric intake of WT and CD1d-null mice on the LFD and HFD regimens. (C) Epididymal fat pad weights of the WT and CD1d-null mice on a LFD and HFD regimen, measured after termination. (D and E) IP-GTTs were performed after 17 weeks of LFD or HFD. Plasma glucose concentrations and the AUC for the various groups are shown. (F and G) Plasma insulin levels during the IP-GTT are shown, together with the AUC. (H and I) IP-GTT of WT and Jx18-null mice after 18 weeks of LFD. Shown are plasma glucose concentrations and the AUC for the 2 groups. n = 15 mice per group; total 30 mice. (J and K) IP-GTT of WT (Isotype) and iNKT cell–depleted (αNK1.1) WT mice. Note that this antibody also depletes NK cells. Shown are plasma glucose concentrations and the AUC for the 2 groups. n = 10 mice per group; total 20 mice. *P < 0.05.
of Tregs in the WT mice on a LFD had no effect (Supplemental Figure 3D). Taken together, the results indicated that CD1d-null mice on a LFD have a unique AT phenotype that, unlike the well-studied HFD phenotype, is characterized not by increased influx of proinflammatory CD8+ T cell or macrophage populations, but rather by increased Treg numbers. The increase in AT Tregs observed upon iNKT cell depletion may serve to prevent further aggravation of insulin resistance.

Absence of CD1d-restricted iNKT cells is associated with adipocyte dysfunction in lean mice. Using an Affymetrix microarray platform, we explored further the AT phenotype in CD1d-null mice on a LFD. Microarray analysis underscored that the AT phenotype
in lean insulin-resistant CD1d-null mice is different from the HFD-associated disease pattern. Classical inflammatory markers upregulated under HFD conditions, including Tnfα, Emr1 hormone receptor (F4/80), integrin alpha X (Cd11c), Cd2, serum amyloid a 3 (Saa3), and a disintegrin and metallopeptidase domain 8 (Adam8) (39–41) were not different in LFD-fed CD1d-null mice and their WT counterparts (Figure 4, A and B). The effect of long-term HFD on the transcriptional profile was remarkably similar (larger area per adipocyte and lower number of adipocytes per field) were found in the CD1d-null mice on a LFD compared with their WT counterparts (Figure 4C and Supplemental Figure 4C), but there was no difference in epididymal fat pad weight (Figure 1C) or total fat mass as determined by dual energy X-ray absorptiometry (DEXA) scanning (Supplemental Figure 4D). No changes in several genes involved in lipogenesis (stearoyl-coenzyme A desaturase 1, Scd1; fatty acid synthase, Fas), lipid droplet formation (perilipin 1, Lipin1, Ppara), and thermogenesis (uncoupling protein 1, Ucp1; Ppara) were detected in LFD-fed CD1d-null mice, except for a significant increase in lipin (Supplemental Figure 4E), an adiposity gene involved in triglyceride synthesis (42). Lipolysis, as determined by plasma glycerol levels, was also not significantly changed (Supplemental Figure 4F). Remarkably, the adipocyte dysfunction in LFD-fed CD1d-null mice was reflected by decreased levels of the insulin-sensitizing adipokine adiponectin and increased levels of the insulin-desensitizing leptin (43), at both the mRNA level in the AT and the protein level in the plasma (Figure 4, D and E). Thus, development of insulin resistance in the absence of iNKT cells may originate from adipocyte dysfunction, in particular altered adipokine secretion. 

Enrichment of CCR2+iNKT cells in human AT. Having investigated mouse AT-resident iNKT cells, we set out to study the role of iNKT cells in human AT. We first assessed the relative number of iNKT cells as a fraction of lymphocytes in paired blood and abdominal SCAT samples obtained from healthy donors (n = 6). iNKT cell numbers were enriched approximately 10-fold in AT compared with blood (flow cytometry analyses, using TCR αβ(β24/Vα11) WT mice. *P < 0.05. 

Figure 3 CD1d-null mice exhibit enhanced AT Treg numbers, preventing worsening of insulin resistance. (A–C) n = 10 mice per group; total 20 mice. (A) Number of CD8+ T cells (TCRβ+) per gram of SCAT and VAT, for WT and Cd1d−/− mice on a LFD. (B) Number of macrophages (F4/80+) per gram of SCAT and VAT, and percentage of M1-polarized (CD11c+) macrophages for WT and Cd1d−/− mice on a LFD. (C) Number of CD4+CD25+ T cells (TCRβ+) per gram of SCAT and VAT for WT and Cd1d−/− mice on a LFD. (D) Representative results of staining of Foxp3 and CD25 expression on AT-derived CD4+ T cells (TCRβ+) in Cd1d−/− mice. (E) Number of Tregs (TCRβ+CD4+Foxp3+) per gram of VAT for WT (Isotype) and iNKT cell–depleted (αNKT1.1) WT mice, n = 10 mice per group; total 20 mice. (F and G) IP-GTT of Cd1d−/− (Isotype) and Treg-depleted (αCD25) Cd1d-null mice on a LFD. Shown are plasma glucose and insulin concentrations, together with the AUC for the 2 groups. n = 10 mice per group; total 20 mice. *P < 0.05.
kinin receptors and CD62L and CD11b were similar in iNKT cells from AT and blood (Figure 5D and Supplemental Figure 5A). Thus, MCP-1/CCR2-mediated and CXCR2- and CXCR6-mediated chemotaxis may provide a mechanism for the recruitment of iNKT cells to AT.

**Figure 4**
Absence of CD1d-restricted iNKT cells is associated with adipocyte dysfunction in lean mice. (A) Microarray-based fold change versus fold change scatter plot comparing gene expression profiles in WT HFD group (x axis) and Cd1d−/− LFD group (y axis). Genes of interest encoding classical inflammatory markers or adipokines are highlighted in red (upregulated) or blue (downregulated). Fold changes represent the mean of 4–6 mice per experimental group. (B) Quantitative RT-PCR of selected classical inflammatory markers in AT. Mean expression in WT LFD mice was set at 1. Fold changes were normalized for housekeeping gene expression (36B4). n = 9 mice per group; total 27 mice. (C) H&E staining of VAT from WT and CD1d-null mice after 19 weeks of LFD feeding. Scale bars: 100 μm. VAT adipocyte sizes (area per adipocyte, μm²) in LFD-fed WT and CD1d-null mice are presented. Box plots show the median area per adipocyte for both groups, and 10th to 90th percentiles. n = 10 mice per group; total 20 mice. (D and E) Leptin and adiponectin mRNA expression in VAT were determined by quantitative RT-PCR (n = 9 mice per group; total 27 mice). Leptin and adiponectin protein levels were analyzed in plasma from LFD-fed CD1d-null mice and WT mice on a LFD and HFD. n = 10 mice per group; total 30 mice.

**Human adipocytes express CD1d and can regulate iNKT cell function.** Adipocytes are a major constituent of AT and contain lipids that may serve as CD1d antigenic ligands. Therefore, we tested the possibility that adipocytes directly modulate iNKT cell function by presenting lipid antigens. First, the expression of CD1d and its
lipid-loading machinery was analyzed in human SGBS (pre)adipocytes, a well-established adipocyte cell culture model (46), and in human primary adipocytes by quantitative RT-PCR. Several known components required for antigen loading (pro-saposin, NPC2, α-galactosidase) as well as CD1D itself were expressed at background levels in undifferentiated preadipocytes, but were readily detectable in mature human SGBS adipocytes and primary adipocytes (Figure 6A). Of note, CD1d depletion by lentivirally transduced CD1d shRNA in human preadipocytes did not influence their differentiation potential, adipocyte marker expression, or adiponectin secretion, suggesting that CD1d expression is not essential for differentiation and function of cultured (pre) adipocytes (Supplemental Figure 5, B and C). The upregulation of CD1d and its loading machinery as measured by increased mRNA gene transcription in mature human adipocytes suggests that adipocytes can function as lipid APCs for iNKT cells. To test this possibility, we generated short-term iNKT cell lines (>70% CD1d-restricted iNKT cells) from 5 healthy blood donors (47) and cocultured them with human adipocyte cell lines, where indicated displaying reduced CD1d expression upon shRNA-mediated knockdown or overexpressing CD1d (Supplemental Figure 5B and Supplemental Figure 6A). After loading of mature adipocytes with α-GalCer (48) and 18 hours of coculture, the production of IL-4, IL-13, and IFN-γ by the iNKT cells was assessed. Strikingly, iNKT cells cocultured with mature adipocytes showed the highest intracellular IL-4, IL-13, and IFN-γ levels. The intracellular cytokine levels were found to be reduced upon CD1d blocking and depleted to background levels by CD1d knockdown (Figure 6B and Supplemental Figure 6B). Interestingly, basal cytokine levels were also decreased by CD1d knockdown, suggesting that adipocytes can present lipid autoantigens (Figure 6B and Supplemental Figure 6B). Cytokine measurements in the supernatant were affirmative, again showing only IL-4, IL-13, and IFN-γ release for iNKT cells cocultured with mature adipocytes. Also here cytokine release was reduced upon CD1d blocking and fully depleted by CD1d knockdown (Figure 6C and Supplemental Fig-
Discussion

In recent years, various AT-resident immune cells have been implicated in the regulation of lipid and glucose homeostasis (9, 13, 14). Here we show that AT-resident CD1d-restricted iNKT cells protect against the development of insulin resistance by preventing adipocyte dysfunction, especially under LFD conditions. The high numbers of CD1d-restricted iNKT cells in both mouse and human AT raise three interesting questions.

First, why do iNKT cells accumulate in AT? The abundance of lipid antigens, together with the lipid APC function of CD1d-proficient adipocytes, may contribute importantly to this phenomenon. In mouse and human liver, lipid processing and high CD1d expression by various cell types also create an iNKT niche (48, 49). Moreover, the enrichment of CCR2+ iNKT cells in human adipose tissue has been associated with obesity (13, 14).

Second, how do iNKT cells modulate lipid metabolism? In this study, we showed that adipocytes can modulate iNKT cell function in a CD1d-dependent manner. This could occur through direct cell-cell interactions or indirect signaling mechanisms. Understanding the molecular basis of this interaction is crucial for unraveling the complex networks of immune and metabolic regulation in AT.

Finally, what is the role of iNKT cells in other tissues? iNKT cells have been reported to play a role in other organs, such as the heart and pancreas, where they contribute to the regulation of inflammation and insulin resistance. Further studies are needed to determine the extent of iNKT cell involvement in the regulation of lipid and glucose metabolism in various tissues.

In conclusion, our findings highlight the importance of AT-resident immune cells in the regulation of lipid and glucose homeostasis. The development of therapeutic strategies targeting iNKT cells could potentially offer novel approaches for the treatment of insulin resistance and related metabolic disorders.
AT suggests chemotaxis by AT-secreted MCP-1, reminiscent of AT-resident macrophages (50). The plethora of AT-secreted factors (43) may well include additional molecules affecting chemotaxis, proliferation, and function of AT-resident iNKT cells. Second, are liver or muscle, as important regulators of glucose tolerance along with AT, involved in the insulin resistance observed in CD1d-null mice? LFD-fed CD1d-null mice showed none of the pathological alterations associated with liver-mediated insulin resistance. A primary role for muscle tissue, another key regulator of whole-body insulin sensitivity, also seems unlikely, as iNKT cell numbers in muscle appear to be low (51). Nevertheless, we cannot exclude secondary roles for the liver and muscle in the insulin resistance following CD1d deficiency. As in obesity, the adipocyte dysfunction in the LFD-fed CD1d-null mice, characterized by adipocyte hypertrophy and altered adipokine secretion, may well affect the insulin sensitivity of secondary tissues such as liver and muscle (1, 43). We have thereby come to the third question.

What function do iNKT cells exert in AT? Our results indicate that iNKT cells should be included in the list of AT-resident immune cells mediating glucose tolerance: AT-resident macrophages (15, 16), T cells (9, 13, 14), B cells (52), eosinophils (10), and mast cells (53). AT-resident iNKT cells appear to be unique, though, in their communication with adipocytes. The expression of functional CD1d in adipocytes and modulation of iNKT cell function fuel the hypothesis that adipocytes, via lipid presentation to iNKT cells, exert control over the local immune response in AT (24). Similar to other tissues (54), iNKT cells may exert immunoregulatory roles in concert with AT-resident Tregs. Indeed, the increased Treg numbers in AT upon depletion or knockdown of iNKT cells suggest partial compensation of the iNKT loss by Tregs. Accordingly, depletion of AT-resident Tregs in CD1d-null mice on a LFD aggravated the already existing insulin resistance. The adipocyte dysfunction in CD1d-null mice observed here, however, also fuels an alternative hypothesis. Along with indirectly affecting adipocyte function via immune modulation, iNKT cells may also directly control adipocyte function: the iNKT cytokine IL-4, secreted at high levels by AT-resident compared with spleen-derived iNKT cells, is known to improve insulin sensitivity via STAT6 activation (55). IL-13, which is also produced by AT-resident iNKT cells under basal conditions, may also affect adipocyte function, but this area has not been explored so far. Interestingly, we found that AT-resident iNKT cells are also capable of producing IFN-γ when stimulated with αGalCer. As IFN-γ has been associated with insulin resistance in cultured adipocytes (56, 57) and in vivo (14, 58), these findings suggest that, in contrast to the protective role we observed under LFD conditions, iNKT cells could contribute to the development of insulin resistance under other conditions. Indeed, some recent reports indicate that depletion of iNKT cells can improve insulin sensitivity under HFD conditions (59–61). The exact role of iNKT cells under HFD conditions is, however, unclear, as other studies, and the present study, failed to detect a prominent effect of iNKT cell depletion on glucose homeostasis (26–28). Of note, the decreased number of AT-resident iNKT cells in obese human individuals and in mice under long-term HFD conditions may explain the marginal effects of iNKT cell depletion under HFD conditions (refs. 25, 26, and the present study). Future studies are required to establish the exact roles of iNKT-produced cytokines in mediating adipocyte (dys)function and insulin resistance under HFD conditions.

Finally, iNKT cells are known to bridge innate and adaptive immunity, as they can rapidly release high doses of immune polarizing cytokines upon lipid/CD1d complex binding (17–19). Upon prolonged stimulation, iNKT cell numbers are known to decrease and iNKT cells become anergic (62). This physiological role of iNKT cells, together with the insulin-resistant phenotype of CD1d-null iNKT cell–deficient mice under LFD conditions, supports a key role for AT-resident iNKT cells as a first line of defense against adipocyte dysfunction, AT inflammation, and insulin resistance. Importantly, AT-resident iNKT cell function seems to depend on diet composition, duration of the diet, and possibly also indigenous gut microbiota (63). The protective role of iNKT cells appears most explicit under long-term LFD conditions, as Kotas et al. recently failed to observe a protective role of iNKT cells under normal chow conditions in 7- to 10-week-old mice (28). The anti-inflammatory phenotype of AT-resident iNKT cells we observed under unstimulated conditions, with high IL-4 and IL-13 production, together with the strong upregulation of IFN-γ production upon stimulation with the exogenous lipid antigen αGalCer, fuels the hypothesis that AT-resident iNKT cell function is determined by dietary factors, possibly in combination with AT lipid autoantigens. The capacity of adipocytes to modulate iNKT cell function in a CD1d-mediated fashion offers a tempting adipocyte-centered perspective on the mechanisms behind iNKT cell activation. CD1d-dependent adipocyte–iNKT cell interactions may play a key role in the maintenance of healthy AT under LFD conditions.

Methods
Animal studies. WT C57BL/6J mice (8 weeks; Charles River), CD1d-null mice (30), and Jtc18-null mice (31) that had been backcrossed to C57BL/6J for 10–12 generations were age matched and fed standard chow until age 10–11 weeks and subsequently fed a LFD (10 kcal% fat; Research Diets, D12450B) or HFD (45 kcal% fat; Research Diets, D12451) for 18–19 weeks. For the IP-GTT, mice (age 28 weeks) were fasted overnight, glucose was injected intraperitoneally (0.5 g/kg body weight), and blood glucose levels were measured before and at multiple time points after glucose injection (Accu-chek, Roche). Plasma was frozen at multiple time points for insulin measurements. For the iNKT cell and Treg depletion studies (Figure 1, J and K, Figure 3, F and G, Supplemental Figure 1A, and Supplemental Figure 3C), WT C57BL/6J mice (8 weeks; Charles River) were fed standard chow until age 10 weeks and subsequently fed LFD for 6 weeks. In the fifth week of LFD feeding, weight-matched groups received 3 intraperitoneal injections of 300 µg αtNK1.1 antibody (clone PK136), 3 injections of 250 µg αCD25 antibody (clone PC61), or isotype antibody injections, in agreement with established iNKT and Treg depletion models (32, 64). (Note that the αtNK1.1 antibody also depletes NK cells.) In the sixth week of LFD feeding, all mice underwent an IP-GTT (1 g/kg body weight glucose) before sacrifice. For the in vivo challenge with αGalCer, WT C57BL/6J mice (10 weeks) fed LFD for 18 weeks were injected intraperitoneally with either vehicle (PBS; n = 10) or αGalCer (n = 10) and underwent an IP-GTT (1 g/kg body weight glucose) 3 days afterward. For DEXA, fat mass was measured by DEXA scan under general anesthesia (isoflurane/N2O/O2) using a PIXImus imager (GE Lunar).

Isolation of mouse leukocytes and flow cytometry. Murine visceral (epididymal) and subcutaneous AT was collected, washed in PBS, and digested for 45 minutes with collagenase type II (Sigma-Aldrich) and DNase I (Roche). Stromal vascular cells (SVCs) were pelleted by centrifugation, incubated for 20 minutes with NH2Cl erythrocyte lysis buffer, and passed through a 100-µm cup filter (BD). Simultaneously, spleens were minced through a 70-µm mesh filter (BD) and collected in NH2Cl lysis buffer. Subsequently,
AT SVCs and spleen cells were washed in FACS buffer (2% fetal calf serum and 0.1% NaN3 in PBS); preincubated with 10% rat serum in FACS buffer; and stained with mAbs specific for TCRβ, NK1.1, CD3, CD8, CD4, CD25, and a CD1d tetramer (NIH) for lymphocyte phenotyping (for some samples, this was followed by intranuclear staining of Foxp3) or stained with mAbs for CD206, F4/80, TCRβ, a CD1d tetramer (NIH), CD150, and CD11c for macrophage phenotyping. Cells were analyzed by flow cytometry with a FasCanto II (BD) flow cytometer and FACSDiva (BD) and FlowJo (Tree Star Inc.) software.

αGalCer stimulation of iNKT cells for intracellular staining. WT C57BL/6J mice (10 weeks, n = 4) were injected peritoneally with either 5 µg αGalCer (n = 4) or vehicle (n = 4). The next day, the mice were sacrificed, and AT SVCs and spleen cells were extracted and dissolved in RPMI medium containing 10% fetal calf serum, 1% penicillin/streptomycin, and 0.1% GolgiPlug (BD) for 2 hours. Subsequently, after preincubulation with 10% rat serum in FACS buffer, cells were stained with mAbs for TCRβ, NK1.1, and a CD1d tetramer (NIH) to identify the iNKT cells, followed by intracellular staining for IL-4 (BD), IFN-γ (BD), IL-13 (BioLegend), and the corresponding isotype antibodies to determine intracellular iNKT cytokine levels.

Ex vivo stimulation and intracellular cytokine staining of AT-resident iNKT cells. Extracted AT SVCs and spleen cells of WT C57Bl/6J mice (9 weeks, n = 4) were dissolved in RPMI medium including 10% fetal calf serum and 1% penicillin/streptomycin, and incubated with 5 ng/ml PMA, 1 µg/ml ionomycin, and 0.1% GolgiStop (BD) for 4 hours. Subsequently, intracellular cytokine levels were measured as described above for the αGalCer stimulation.

RNA extraction, quantitative PCR, and microarray analysis. Snap-frozen epididymal AT was homogenized and RNA was extracted using TRIzol (Invitrogen). RNA was purified on a RNasy Micro column (QiAGEN). RNA integrity was checked with a Bioanalyzer (Agilent), and cDNA synthesis was performed with iScript (Bio-Rad). Quantitative PCR with SYBR Green (Bio-Rad) was run on a MyQ machine (Bio-Rad). Primers for quantitative RT-PCR were designed with the universal probe library (Roche) and are described in Supplemental Table 1. Microarray experiments were performed as described before (65). RNA samples from 4–6 mice per experimental group were used for microarray analysis. One hundred nanograms of RNA per sample was hybridized to an Affymetrix Chip GeneChip Mouse Gene 1.1 ST 24 array plate according to the manufacturer’s instructions. Arrays were normalized with the robust multiarray average (RMA) method (66, 67). Probe sets were defined according to Dai et al. (68) with CDF version 74. The microarray data have been submitted to the Gene Expression Omnibus database (GEO number GSE39534).

Mouse plasma measurements. Mouse EDTA plasma was harvested after centrifugation and stored at −80°C until analysis. Mouse plasma adipokines were measured with Milliplex mouse adipokine kits (Millipore), according to the manufacturer’s instructions. Measurements and data analysis were performed on a Bio-Plex system in combination with Bio-Plex manager software version 4.1.1 (Bio-Rad). AST and ALT levels in mouse EDTA plasma were measured at the diagnostic laboratory of the University Medical Centre Utrecht with a Beckman Coulter DxC chemistry analyzer. Plasma lipoproteins were separated using fast protein liquid chromatography (FPLC). Pooled plasma (0.2 ml) was injected into a Superose 6B 10/300 column (GE Healthcare Life Sciences) and eluted at a constant flow of 0.5 ml/min with PBS (pH 7.4). The effluent was collected in 0.5-ml fractions and FFA, triglyceride, and cholesterol levels were determined (Instruchemie). Plasma glycerol was measured with a commercially available kit from Instruchemie.
Acknowledgments

The authors thank members of the Prakken, Boes, and Kalkhoven laboratories for helpful discussions and the NIH Tetramer Facility for providing the CD1d tetramers. We also thank A. Ostroveanu, S. Versteeg, A. van der Sar, R. Wichers, J. Tasdelen (University Medical Centre Utrecht), and W. Dijk (Wageningen University, Wageningen, the Netherlands) for technical assistance; M.V. Boekschoten (Wageningen University) for help in analyzing the microarray data; and L. Meij and C. Resius (Bergman Beauty Clinics, Bilthoven, the Netherlands) for assistance with patient recruitment. We thank A. Oosting (Danone, Wageningen) for assistance with DEXA. This study was supported by the research program of The Netherlands Metabolomics Centre, which is part of The Netherlands Genomics Initiative (NGI)/Netherlands Organization for Scientific Research (NWO), and by the Dutch Technology Foundation (STW), which is the applied science division of NWO, and the Technology Programme of the Ministry of Economic Affairs.
