We present measurements of lepton ($\ell$) angular distributions in $t\bar{t} \rightarrow W^+bW^−\bar{b} \rightarrow \ell^+\nu\ell^−\bar{\nu}b\bar{b}$ decays produced in $p\bar{p}$ collisions at a center-of-mass energy of $\sqrt{s} = 1.96$ TeV, where $t$ is an electron or muon. Using data corresponding to an integrated luminosity of 5.4 fb$^{-1}$, collected with the D0 detector at the Fermilab Tevatron Collider, we find that the angular distributions of $\ell^-$ relative to anti-protons and $\ell^+$ relative to protons are in agreement with each other. Combining the two distributions and correcting for detector acceptance we obtain the forward-backward asymmetry $A_{FB}^\ell = (5.8 \pm 5.1$ (stat) $\pm 1.3$ (syst))%, compared to the standard model prediction of $A_{FB}^\ell$(predicted) = (4.7 (0.1)%). This result is further combined with the measurement based on the analysis of the $\ell$+jets final state to obtain $A_{FB}^\ell = (11.8 \pm 3.2)$%. Furthermore, we present a first study of the top-quark polarization.

To check the validity of the standard model (SM) of elementary particle physics and to search for possible extensions, we measure the properties of the top ($t$) quark. At leading order (LO) in perturbative quantum chromodynamics (QCD), production of $t\bar{t}$ pairs through quark-antiquark ($q\bar{q}$) annihilation is expected to be forward-backward (FB) symmetric in the center-of-mass frame. At next-to-leading order (NLO) QCD, interference leads to a positive FB asymmetry, which implies that the top (antitop) quark is emitted with higher probability in the direction of the incoming quark (antiquark). Top pair production through gluon-gluon fusion does not lead to such asymmetry.

SM predictions for the FB asymmetry can be modified by processes beyond the SM [1, 2], such as contributions from hypothesized axigluons [3], $Z'$ or $W'$ bosons [4], and new scalars [5]. These sources of physics beyond the SM modify observables sensitive to the top quark polarization [6].

At the Tevatron $p\bar{p}$ collider, with $\sqrt{s} = 1.96$ TeV, $t\bar{t}$ production is dominated by $q\bar{q}$ annihilation. The direction of the incoming quark (antiquark) therefore coincides with the direction of the proton (antiproton). The $t$ quark (antiquark) is more likely to be emitted in the direction of the incoming quark (antiquark) than in the opposite direction. This FB asymmetry in $t\bar{t}$ production can also be observed through the $t$ and $\bar{t}$ decay products, for example, in the distributions of charged leptons ($\ell = e, \mu$) from $t \rightarrow W^+b \rightarrow \ell^+\nu\ell^−\bar{\nu}b$ and $\bar{t} \rightarrow W^−\bar{b} \rightarrow \ell^−\bar{\nu}\ell^+\nu$.

decays.

The CDF and D0 Collaborations have previously performed measurements of the FB asymmetry in $t\bar{t}$ decays to $\ell+\text{jets}$ final states containing exactly one lepton, jets and an imbalance in transverse momentum ($E_T$) [7–9]. The asymmetries reported by both Tevatron collaborations are larger than predicted in NLO QCD. The asymmetry in CDF data at large values of $t\bar{t}$ invariant mass ($m_t > 450$ GeV) differs by more than three standard deviations (SD) from the NLO prediction [7]. The D0 data show no significant excess in this mass range. Defining a $t\bar{t}$ asymmetry based on the pseudorapidity, $\eta$ [10], of the charged lepton, D0 finds a significant deviation from NLO QCD predictions of the order of three SD [8]. The ATLAS and CMS collaborations have performed measurements of the difference in angular distributions between top quarks and antiquarks in the $\ell+\text{jets}$ final state using asymmetries based on the top quark and antiquark rapidities [11, 12] and pseudorapidities [12]. The results are consistent with the SM expectations.

In this Letter, we present six measurements of leptonic FB asymmetries in $p\bar{p}$ collisions at $\sqrt{s} = 1.96$ TeV, using data corresponding to an integrated luminosity of 5.4 fb$^{-1}$, collected with the D0 detector in Run II of the Fermilab Tevatron Collider. We use $t\bar{t}$ candidates in dilepton final states, where the $W$ bosons from $t$ and $\bar{t}$ decays both decay into $e\nu_e$, $\mu \nu_\mu$, or $\tau \nu_\tau$, and the $\tau$ lepton decays leptonically ($\tau \rightarrow \ell\nu_\ell q_\ell$). We calculate asymmetries based on the pseudorapidity and charge of the electrons or muons. These asymmetries are determined from the angles of the charged leptons, which are measured with high resolution. These measurements have the advantage that a full reconstruction of the $t\bar{t}$ event is not required. In addition, we combine this measurement of the FB asymmetry with the D0 measurement performed in $\ell+\text{jets}$ final states [8]. Furthermore, we present a first study of the longitudinal polarization of the top quark.

A description of the D0 detector can be found in [13]. The selection criteria and object identification of the dilepton ($ee, e\mu, \mu\mu$) decay channels follow those described in Ref. [14]. To enrich the sample in $t\bar{t}$ events, we require two isolated, oppositely charged leptons with transverse momentum $p_T > 15$ GeV and at least two jets with $p_T > 20$ GeV and detector pseudorapidity $|\eta_{\text{jet}}| < 2.5$ [10]. For the $e\mu$ channel we require that $H_T$ (defined as the scalar sum of the larger of the two lepton-$p_T$ values and the scalar $p_T$ of each of the two most energetic jets) be greater than 110 GeV. For $ee$ and $\mu\mu$ events we compute a likelihood for the significance of $E_T$ [15], based on the probability distribution calculated from the value of $E_T$ and the lepton and jet energy resolutions. We require this likelihood to exceed the value typical for background events. We find that only the $\mu\mu$ channel benefits from an additional restriction on $E_T$ and, to increase signal purity, we therefore require $E_T > 40$ GeV for the $\mu\mu$ final state. We select a $t\bar{t}$ sample with a signal to background ratio of 3.2, 3.7 and 0.9 in the $ee$, $e\mu$ and $\mu\mu$ final states, respectively.

To simulate $t\bar{t}$ production, the mc@nlo [16] generator is used assuming $m_t = 172.5$ GeV. The production of top quarks is simulated at NLO, while the decay is simulated only at LO. To include full NLO QCD corrections to both production and decay as well as mixed QCD and quantum electrodynamic corrections and mixed QCD and weak corrections to the production amplitudes (denoted by “QCD+EW”), we simultaneously correct the normalized lepton and antilepton rapidity distributions in mc@nlo using the predictions of Ref. [17]. HERWIG [18] is used to simulate fragmentation, hadronization and decays of short-lived particles, and the generated events are processed through a full detector simulation using GEANT [19]. The Monte Carlo (MC) events are overlaid with data from random bunch crossings to model the effect of detector noise and additional pp interactions. The same reconstruction programs are then applied to data and MC events. The background in the dilepton channel arises from $Z/\gamma^* \rightarrow t\bar{t}\ell\ell$ and diboson events ($WW$, $WZ$ and $ZZ$) with associated jets, from instrumental background where a jet is misidentified as a lepton, and from heavy quarks that decay into leptons that pass isolation requirements. A detailed description of these processes and their generation can be found in Ref. [20].

Leptons are reconstructed with excellent resolution on the measurements of their angles and electric charge. In contrast, it is challenging to reconstruct the four-momenta of the $t$ and $\bar{t}$ quarks, since the kinematics is underconstrained because of the two neutrinos in the final state. Rather than reconstructing the $t$ and $\bar{t}$ four-momenta, as in Refs. [7–9], we measure observables correlated to the FB asymmetry, which depend solely on the $\eta$ and electric charge of the lepton $\ell$, as proposed in Ref. [6]. The asymmetry for leptons is defined as:

$$A^\ell = \frac{N_{\ell^+}(\eta > 0) - N_{\ell^-}(\eta > 0)}{N_{\ell^+}(\eta > 0) + N_{\ell^-}(\eta > 0)}, \tag{1}$$

where $N_{\ell^+}(\eta)$ and $N_{\ell^-}(\eta)$ correspond to the number of leptons and antileptons as a function of $\eta$, respectively. If CP invariance holds in $t\bar{t}$ production and decay, then $N_{\ell^+}(\eta) = N_{\ell^-}(\eta)$, and $A^\ell_{FB}$ defines the FB asymmetry for both leptons:

$$A^{±}_{FB} = \frac{N_{\ell^\pm}(\eta > 0) - N_{\ell^\mp}(\eta < 0)}{N_{\ell^\pm}(\eta > 0) + N_{\ell^\mp}(\eta < 0)}. \tag{2}$$

The asymmetries $A^{+}_{FB}$ and $A^{-}_{FB}$ are statistically independent and opposite. We can therefore combine the asymmetries for $\ell^+$ and $\ell^-$ by multiplying $\eta$ with the charge $Q$ of each lepton:

$$A^\ell_{FB} = \frac{N_{\ell}(Q \cdot \eta > 0) - N_{\ell}(Q \cdot \eta < 0)}{N_{\ell}(Q \cdot \eta > 0) + N_{\ell}(Q \cdot \eta < 0)}. \tag{3}$$
we define an angular asymmetry for leptons:

$$A^\ell = \frac{N(\Delta \eta > 0) - N(\Delta \eta < 0)}{N(\Delta \eta > 0) + N(\Delta \eta < 0)},$$

where $\Delta \eta = \eta^+ - \eta^-$. The asymmetry $A_{\text{CP}}^\ell$ corresponds to a longitudinal asymmetry in spin orientation relative to the proton beam direction. It is defined as:

$$A_{\text{CP}}^\ell = \frac{N_{\ell^+}(\eta > 0) - N_{\ell^-}(\eta < 0)}{N_{\ell^+}(\eta > 0) + N_{\ell^-}(\eta < 0)}.$$

This asymmetry is sensitive to $s$-channel exchanges of heavy non-scalar resonances with CP-violating couplings to quarks, but not to possible P and CP-violating effects from an $s$-channel exchange of Higgs bosons [6].

The asymmetries are measured in four ways using $\eta$ and $Q$ of the leptons: separate $\eta$ distributions for (i) $\ell^+$ and (ii) $\ell^-$, (iii) the charge-signed pseudorapidity, $Q \cdot \eta$, and (iv) $\Delta \eta$. They are presented in Fig. 1. To extract the asymmetries for $t\bar{t}$ events from the distributions shown in Fig. 1, we subtract the background and then correct for effects from event reconstruction and acceptance. The correction for detector acceptance is performed by multiplying the background-subtracted number of events with the inverse of the selection efficiency. This is calculated using $t\bar{t}$ MC events, where we evaluate the selection efficiency separately for twenty bins in lepton $\eta$, to reduce the model dependence of our acceptance correction and to provide sufficient MC statistics.

The resolution of the measurement of lepton $\eta$ is obtained from studies of $t\bar{t}$ MC events by comparing the generated value of $\eta$ with the value measured following event reconstruction. For electrons and muons, we use the $\eta$ of tracks measured in the tracking system and find this resolution to be the same for both types of leptons. This resolution is also investigated using cosmic-ray muons that appear as dimuon events and is found to be approximately 0.0026, consistent with the MC expectation. For approximately 99.8% of the electrons or muons in $t\bar{t}$ MC events, the sign of lepton $\eta$ is correctly reconstructed. Migration of events within the “forward” or “backward” regions does not affect the reconstructed angular asymmetry except for negligible acceptance corrections. The reconstruction effects on the measurement of $\eta$ can therefore be neglected for charged leptons.

The $Z$+jets background, which is predicted through MC simulation [20], contributes to the asymmetry. To study the influence of the $Z$+jets background, we perform measurements of all six asymmetries in a sample dominated by $Z$+jets production in final states with two electrons or two muons. Applying the same event selections as for the final $t\bar{t}$ enriched sample, except for the $E_\text{T}$ significance likelihood and $E_\text{T}$ requirements, all asymmetries are measured using the same procedure as for the measurement of $t\bar{t}$ asymmetries, but treating $Z$+jets as “signal” and $t\bar{t}$ as “background”. In this control sample, all other background contributions are negligible. The data and MC predictions for the $\eta$ distribution of positively and negatively charged leptons, for $Q \cdot \eta$, and $\Delta \eta$, are in good agreement, as presented in [21].

To verify that the measurement of the $t\bar{t}$ asymmetries is unbiased and correctly estimates the statistical uncertainty of the result, we perform the measurement using ensembles of MC pseudo-experiments. To obtain samples with different asymmetries, we mix a $t\bar{t}$ MC event sample weighted to have no asymmetry with different fractions of $t\bar{t}$ MC events with a SM asymmetry. We fluctuate the expected number of events in the “forward” and “backward” direction for each pseudo-experiment assuming Poisson statistics and apply the same procedure as for data to extract the asymmetry. This test shows that the measurement is unbiased and that the statistical uncertainties are estimated correctly.

Systematic uncertainties can affect the distributions in lepton $\eta$. In particular, the energy scale for jets, jet energy resolution, jet reconstruction, the normalization of background, the MC-derived acceptance, and the finite number of MC events can shift the measured asymmetry. The normalization of the background has uncertainties from diboson and $Z$+jets cross sections, as well as a 6.1% uncertainty on the data sample’s integrated luminosity. The systematic uncertainties on the light and heavy-flavor jet energy scales, jet energy resolution, and the jet reconstruction can affect the acceptance. We evaluate the size of these uncertainties by applying the variation in acceptance corrections and in the differential distribution of lepton $\eta$ in deriving the $t\bar{t}$ asymmetry.

In addition, we compare the acceptance from single leptons obtained from simulated $t\bar{t}$ events with the accep-
of the uncorrected asymmetries as well as the un-
given in Table 1.

The systematic uncertainties are added
in quadrature to yield the total systematic uncertainties
trons and muons. The systematic uncertainties are added

The acceptance between the forward and backward hemisphere of
leptons. A systematic uncertainty on the acceptance is

defined for each lepton charge by the difference in accep-
tivities, nor between positively and negatively charged

The asymmetry \( A^\ell_{FB} \) in Eq. (2) is also mea-
sured in \( \ell+\)jets final states [8]. The result for \( A^\ell_{FB} = (15.2 \pm 4.0)\% \) is compared to a predicted value from

\[ A^\ell_{FB} = (11.8 \pm 3.2)\% \text{, where the } \ell+\text{jets channel contributes 63.9}\% \text{ and the dilepton channel 36.1}\% \text{ of the information.} \]

This represents an improvement of about 20\% relative to the uncertainty in the \( \ell+\)jets channel alone. The consistency between the two individual measurements is 68\%.

Comparing the combined result to the predicted leptonic FB asymmetry from MC@NLO plus higher order QCD+EW corrections, \( A^\ell_{FB}(\text{predicted}) = (4.7 \pm 0.1)\% \), we observe a disagreement at the level of 2.2 SD.

To further investigate this deviation of the asymmetry from the SM prediction, we analyze the longitudinal polar-
ization of the top quark. While in the SM top quarks are expected to be produced unpolarized in \( t\bar{t} \) events, there are many beyond the SM models that would en-
hance the \( t\bar{t} \) FB asymmetry [1] and therefore the leptonic asymmetries defined in Eqs. (1)-(5), and would also lead to a non-vanishing longitudinal polarization of the top quark. Examples are models with new parity-
vio1ating interactions. In the absence of effects from ac-
ceptance, the distribution of \( \cos \theta^- \) and \( \cos \theta^+ \) should be isotropic [6] for unpolarized top quarks, where \( \theta^- \) is the angle between the direction of the \( \ell^- (\ell^-) \) in the \( t (\bar{t}) \) rest frame and the \( \ell \) direction in the \( t\bar{t} \) rest frame.

A longitudinal polarization of the top quark would cause asymmetric \( \cos \theta^\pm \) distributions.

Assuming CP invariance, i.e. that the distributions of \( \cos \theta^+ \) and \( \cos \theta^- \) are equal, we measure the distribution \( \cos \theta \), defined by the sum of the \( \cos \theta^\pm \) distributions. The calculation of the angles \( \theta^\pm \) requires a transformation of the momenta of the charged leptons into the \( t \) and \( \bar{t} \) quark rest frames. Every event must therefore be fully reconstructed. This is performed using the neutrino weighting method, devised originally to measure the top quark mass in the dilepton channel [24] and recently ap-
plied to measure \( t\bar{t} \) spin correlations [20].

In Fig. 2, the \( \cos \theta \) distribution is shown separately for the dilepton and \( \ell+\)jets final states. The distribution for \( t\bar{t} \) events produced via a leptophobic topcolor \( Z' \) boson, with the same parity-violating couplings to quarks as the SM \( Z \) boson and a width \( \Gamma = 0.012M_Z \) [25, 26] is also

\[ A^\ell_{FB} = (15.2 \pm 4.0)\% \text{ is compared to a predicted value from} \]

TABLE 2: Measured asymmetries for leptons, as defined in Eqs. (1)-(5), including statistical and systematic uncertainties for the combined dilepton final states using raw and unfolded distributions are compared to predictions from MC@NLO including QCD+EW corrections. Our predictions are calculated using the NLO QCD+EW distributions in both numerator and denominator of Eqs. (1)-(5). This is different to the calculations in Refs. [6, 17] where the denominator is calculated in LO QCD to derive expressions for the asymmetries of \( \mathcal{O}(\alpha_s) \). All values are given in %.

We find the leptonic FB asymmetry $A_\ell^\ell$ in agreement with the SM prediction in both distributions of charged leptons. We distinguish detector effects due to the production of $t\bar{t}$ pairs produced via a hypothetical $Z'$ boson is also shown; the uncertainty due to the limited size of the MC sample is shown by the shaded band.

The agreement between the data and the SM prediction in both distributions is good, yielding a Kolmogorov-Smirnov test probability of $8 \pm 3\%$ in the dilepton channel and $58\%$ in the $\ell+{jets}$ channel. There is no significant hint of new sources of parity violation leading to a longitudinal polarization in $t\bar{t}$ production.

In conclusion, we measured angular asymmetries in $t\bar{t}$ production based on $\eta$ distributions of charged leptons. We find the leptonic FB asymmetry $A_\ell^FB$ and the lepton asymmetry $A_\ell^\ell$ in agreement with the SM prediction in the dilepton final state. Combining our measurement of $A_\ell^FB$ with the measurement performed using leptons in $\ell+{jets}$ final states yields $A_\ell^FB = (11.8 \pm 3.2)\%$, which is 2.2 SD above the higher order QCD+EW prediction of $A_\ell^FB(\text{predicted}) = (4.7 \pm 0.1)\%$. The top-quark polarization in the dilepton and $\ell+{jets}$ final states show good agreement between the data and the SM prediction.

We would like to thank W. Bernreuther and Z. G. Si for useful discussions and providing us with the lepton rapidity distributions used for theoretical predictions. We thank the staffs at Fermilab and collaborating institutions, and acknowledge support from the DOE and NSF (USA); CEA and CNRS/IN2P3 (France); FASI, Rosatom and RFBR (Russia); CNPq, FAPERJ, FAPESP and FUNDUNESP (Brazil); DAE and DST (India); Colciencias (Colombia); CONACyT (Mexico); NRF (Korea); CONICET and UBACyT (Argentina); FOM (The Netherlands); STFC and the Royal Society (United Kingdom); MSMT and GACR (Czech Republic); BMBF and DFG (Germany); SFI (Ireland); The Swedish Research Council (Sweden); and CAS and CNSF (China).

[10] The rapidity $y$ and pseudorapidity $\eta$ of a particle are defined as functions of the polar angle $\theta$ with respect to the proton beam direction and velocity $\beta$ by $y(\theta,\beta) = \ln [(1 + \beta \cos \theta)/(1 - \beta \cos \theta)]$ and $\eta(\theta) = y(\theta,1)$, where $\beta$ is the ratio of a particle’s momentum to its energy. We distinguish detector $\eta$ ($\beta$aux) and collision $\eta$, where the former is defined with respect to the center of the detector and the latter with respect to the pp interaction vertex.
[21] See Appendix A for additional figures of the $\eta$ distribution of positively and negatively charged leptons, for $Q$-$\eta$, and $\Delta\eta$, in a sample dominated by $Z$+jets background.
FIG. 3: Rapidity distributions of the charged leptons for the combination of the dimuon and dielectron final states. The final selection requirements have been removed i.e. the $E_T$ significance likelihood cut for the $ee$ and $\mu\mu$ channels and the $E_T$ cut for the $\mu\mu$ final state. The samples are therefore dominated by $Z$+jets events. The pseudorapidity distribution of positively (a) and negatively (b) charged leptons, the distribution of $q \cdot \eta$ (c) and the distribution of $\Delta \eta = \eta_\ell^+ - \eta_\ell^-$ (d) are shown.
