A
ge-related macular degeneration (AMD) is the leading cause of irreversible vision loss in developed countries among individuals older than 50 years.1 AMD is a gradual progressive disease that evolves from early and intermediate stages, with no or subtle visual changes, to an advanced stage, where the loss of central vision can occur. Patients with intermediate AMD are at higher risk of developing advanced AMD and thus suffering from severe visual loss, and they should undergo routine and self-monitoring for a timely diagnosis.2 Lifestyle changes such as cessation of smoking and prophylactic regimen like vitamin supplementation are recommended for patients at risk in order to slow progression of the disease.3–6

Deposits of extracellular material localized between the inner collagenous layer of Bruch’s membrane and the basal lamina of the RPE, known as drusen, are considered the hallmark feature of AMD.7 Macular drusen are important in the context of AMD grading, and certain drusen characteristics are associated with progressing toward end-stage AMD.8–14 On fundus photography they appear as yellowish-white spots, and different drusen phenotypes can be distinguished. Hard drusen are defined as small (<65 μm) nodular lesions with well-defined borders. Soft drusen, on the other hand, tend to be larger, and are generally characterized by poorly demarcated boundaries.7–9,12,15

Identification and classification of eyes with AMD are performed mainly using color fundus images by manually determining the size and extension of drusen.8,12,16–19 However, other imaging modalities, such as optical coherence tomography, are gaining traction as well.20,21 Human observer classification is time-consuming and prone to interobserver variations.22 Aside from speed, objectivity, and reproducibility, implementation of an automatic drusen detection and quantification system could prove useful in many ways. It may allow for a cost-efficient screening program for patients at risk and help identify and classify AMD patients in large cohort studies. Additionally, accurate quantitative measurements can help in large clinical studies for the evaluation and progression of drusen area, for example, in clinical trials concerning new therapeutic strategies for dry AMD, and it could help in applying inclusion criteria for large-scale clinical studies and genotype-phenotype correlation analysis.23

PURPOSE. To evaluate a machine learning algorithm that allows for computer-aided diagnosis (CAD) of nonadvanced age-related macular degeneration (AMD) by providing an accurate detection and quantification of drusen location, area, and size.

METHODS. Color fundus photographs of 407 eyes without AMD or with early to moderate AMD were randomly selected from a large European multicenter database. A machine learning system was developed to automatically detect and quantify drusen on each image. Based on detected drusen, the CAD software provided a risk assessment to develop advanced AMD. Evaluation of the CAD system was performed using annotations made by two blinded human graders.

RESULTS. Free-response receiver operating characteristics (FROC) analysis showed that the proposed system approaches the performance of human observers in detecting drusen. The estimated drusen area showed excellent agreement with both observers, with mean intraclass correlation coefficients (ICC) larger than 0.85. Maximum druse diameter agreement was lower, with a maximum ICC of 0.69, but comparable to the interobserver agreement (ICC = 0.79). For automatic AMD risk assessment, the system achieved areas under the receiver operating characteristic (ROC) curve of 0.948 and 0.954, reaching similar performance as human observers.

CONCLUSIONS. A machine learning system capable of separating high-risk from low-risk patients with nonadvanced AMD by providing accurate detection and quantification of drusen, was developed. The proposed method allows for quick and reliable diagnosis of AMD, opening the way for large dataset analysis within population studies and genotype-phenotype correlation analysis.

Keywords: age-related macular degeneration, drusen detection, risk assessment
Previously proposed methods automatically assessed the presence of drusen on color fundus photographs.24,25 However, the presence of drusen alone is not directly correlated with the risk of progression to advanced AMD.2 Other works focused on the automatic quantification of drusen without identifying patients at high risk or the AMD stage.23,26–32 Here, we describe and evaluate a machine learning algorithm that automatically distinguishes between images from low-risk and those from high-risk AMD patients by providing an accurate quantification of drusen location, area, and size.

Methods

Study Dataset

A total of 407 images of different eyes with nonadvanced stages of AMD (i.e., stages 1, 2, and 3 according to the criteria shown in Table 1),24,25 with sufficient grading quality for human graders, was selected in consecutive fashion from the European Genetic Database (EUGENDA, http://www.eugenda.org), a large multicenter database for clinical and molecular analysis of AMD.33,34 For each subject, images of both eyes were eligible for inclusion, but we did not select multiple images of the same eye. Images with presence of reticular pseudodrusen were excluded from analyses. Number of drusen, age, or ethnicity was not taken into account for the selection of data. Written informed consent was obtained before enrolling patients in EUGENDA. The study was performed according to the tenets set forth in the Declaration of Helsinki, and Investigational Review Board approval was obtained.

Digital nonstereoscopic color fundus photographs were acquired with a TRC 501X model digital fundus camera at 50° (Topcon Corp., Tokyo, Japan) or with a CR-DGi model non-mydriatic retinal camera at 45° (Canon, Inc., Tokyo, Japan), and pupil dilation was achieved with topical 1.0% tropicamide and 2.5% phenylephrine. All images were macula-centered. Image size varied from 1360 × 1024 to 3504 × 2336 pixels. Before analysis, images were resized in a preprocessing step to have a field of view with a standardized diameter of 630 pixels independently of the image resolution. The data were divided randomly into two sets: set A, consisting of 52 images, for the evaluation of automatic drusen quantification, and set B, consisting of 355 images, for the evaluation of automatic risk assessment. Images from the same patients were kept in the same set.

Observer Annotations

Resampled images were displayed on an LCD monitor similar to those used in ophthalmology practice and with the ability to zoom and pan. All visible drusen were manually outlined in set A by both observers using a specifically developed annotation tool. Whether confluent drusen were annotated as separate drusen or as one large drusenoid patch was left to the judgment of the observers. Two trained graders (JPHV, designated Observer 1, and YTEL, designated Observer 2) manually performed a risk assessment to develop late-stage AMD in all images of sets A and B. No AMD and early AMD were defined as low-risk stages, and intermediate AMD was considered high-risk stage. AMD was defined according to the standard protocol of the Cologne Image Reading Center and Laboratory (CIRCL) (Table 1).33 An AMD classification that was adopted specifically for EUGENDA based on different international staging systems.8,16–19 Both observers performed one session of AMD grading for each study eye in set B and performed one session of drusen annotation for each study eye in set A on a different day.

Machine Learning Algorithm

The proposed CAD system analyzed all color fundus images to automatically quantify the visible drusen and assigned each image a probability between 0 and 1, with 1 indicating a high risk of developing advanced AMD and 0 indicating low risk. To accomplish this, the system performed the following steps:

1. Druse candidate extraction: Each pixel in the image was assigned a probability that the pixel was part of a bright lesion structure, using a supervised pixel classification method. Supervised classification is a machine learning technique where manually labeled training examples are used to infer the classification rule.50 Neighboring pixels with similar probability, not located close to the automatically detected optic disc,50 were grouped into druse candidates.

2. Druse candidate segmentation: The boundary of each druse candidate was automatically delineated using intensity and contrast characteristics.

3. Druse candidate classification: Druse characteristics and a supervised lesion classification method were used to assign a probability to each segmented candidate which indicated the likelihood of being a true druse, creating a so-called drusen probability map.

4. AMD risk assessment: Based on the drusen probability map, a supervised image classification method assigned each image a probability to be at high risk of developing advanced AMD.

Figure 1 shows the steps of the CAD algorithm. The classification steps in the system were performed using statistical classifiers that could differentiate between different types of pixels, candidates, or images by using a training set of labeled examples and extracting numerical characteristics.
be found in Appendix A. Given an image, the CAD system provides two outputs: (1) detection of all visible drusen in the image and quantification of the drusen area and maximum druse diameter; and (2) a probability indicating the likelihood that the patient was at high risk of developing advanced AMD based on the drusen probability map.

### Data Analysis

To evaluate the proposed CAD system, two types of analyses were performed: (1) evaluation of automatic drusen quantification; and (2) evaluation of automatic AMD risk assessment. Due to the lack of a single gold standard, each evaluation was performed twice, taking Observer 1 as reference standard and comparing the CAD results with those obtained by Observer 2, and vice versa.

For drusen quantification, a fivefold cross-validation approach was performed to train and test the CAD system by using data from set A. Cross-validation analysis allows determination of the system performance in an unbiased manner. Using the test folds, the lesion sensitivity (fraction of drusen marked in the reference standard that were detected as drusen by the CAD system) and the number of false positives per image were calculated after setting a threshold for the druse probabilities obtained in step 3. Varying this threshold, different lesion sensitivity-false positives pairs were calculated and summarized in a free receiver operating characteristic (FROC) to evaluate the CAD performance on the detection of drusen. The observer performance compared to the reference standard, which corresponds with one lesion sensitivity-false positives pair, was also calculated and included in the obtained FROC curve.

Total drusen area and maximum druse diameter obtained by the CAD system were calculated using the distance between the fovea and the border of the optic disc as a reference distance of 3000 μm. After thresholding the drusen probability map, total drusen area and maximum druse diameter were measured and compared to the observers' opinions, using intraclass correlation coefficient (ICC) analysis. This threshold was set at the same false-positives rate as Observer 1, as this observer had fewer false positives than Observer 2. During the analysis, the performance of the CAD system and the observers of drusen quantification were evaluated inside and outside the Early Treatment Diabetic Retinopathy Study (ETDRS) grid, which was manually set before the analysis.

For AMD risk assessment, a leave-one-out cross-validation approach was performed to train and test the CAD system by using data from set B. The leave-one-out cross-validation allows measurement of the predictive performance measure of a statistical model by testing a single sample while training with the remaining samples. This is repeated such that each sample is used once as test data. Using the test folds, image sensitivity (fraction of images correctly classified by the CAD system in the high-risk stage) and image specificity (fraction of images correctly classified by the CAD system in the low-risk stage) were calculated after setting a threshold for the estimated risk obtained in step 4. Varying this threshold, different image sensitivity-image specificity pairs were calculated and summarized in a receiver operating characteristic (ROC) to evaluate the CAD performance of distinguishing between low-risk and high-risk patients. The area (A) under the ROC was used as a measure of performance. The observer performance compared to the reference standard, which corresponds with one image sensitivity-image specificity pair, was also calculated and included in the obtained ROC curve. Overall agreement on risk assessment between the observers was calculated using Cohen’s κ statistics (version 17.0.0 software; SPSS, Chicago, IL).
RESULTS

Of 407 images, 145 were captured with the Topcon camera, and 262 were captured with the Canon camera. Table 2 shows some statistics of the performed observer annotations for AMD risk assessment and drusen quantification.

Drusen Quantification

Figure 2 shows the drusen automatically detected by the CAD system from a sample image and shows the annotations of the observers. Figures 3A and 3B show the FROC curves for the CAD system inside and outside the ETDRS grid, using Observer 1 and Observer 2 as reference standard, respectively.

Tables 3 and 4 summarize the mean drusen area and maximum druse diameter obtained by the CAD system and the observers. The corresponding ICCs are shown in Figures 4A and 4B. For estimated drusen area, ICCs of 0.91 and 0.86 were obtained for the CAD system compared to Observer 1 and Observer 2, respectively, whereas the interobserver agreement reached an ICC equal to 0.87. The CAD system showed similar agreement with the observers independently of the camera used for the acquisition, reaching ICC values of 0.80 and 0.88 on images acquired with the Topcon digital fundus camera at 50° and the Canon nonmydriatic retinal camera at 45°, respectively. For the estimation of maximum druse diameter, defined as the diameter of the smallest enclosing circle of a druse, the agreement with the observers was lower with a maximum ICC of 0.69, whereas observers had an agreement with ICC of 0.79.
Figures 5A and 5B show ROC curves using Observer 1 and Observer 2 as reference standards, obtaining Az values of 0.948 and 0.954, respectively. Observer 2 reached an image sensitivity of 0.85 and an image specificity of 0.96, as shown in Figure 4, whereas Observer 1 obtained an image sensitivity of 0.84 and image specificity of 0.96 (Fig. 5). Table 5 shows the contingency table and kappa (κ) agreement between the observers and between the CAD system and the observers for AMD risk assessment. The threshold for the CAD system was set at the cutoff point that maximizes sensitivity + specificity.

### DISCUSSION

In this study, a supervised machine learning algorithm for automated AMD classification based on drusen identification and quantification, was developed. Our system was able to perform equally as experienced human graders with respect to AMD risk assessment, drusen localization, and determination of mean drusen area with a dataset considerably larger than those used in previous publications.25–27,29,31,41–46

Detecting drusen on color fundus images is a challenging task, as shown by the differences in observer annotations in Figure 2. These differences illustrate the need for a robust and accurate system for drusen detection. This would help in eliminating intra- and interobserver variability and the subjective character of manual drusen detection. For this reason, automated drusen detection on color fundus photographs has been a field of interest for the last couple of decades. However, many systems still require human adjustments or close supervision by experts and are therefore still amenable to subjective input.26,31,32,44–46 Unsupervised automatic detection systems have been developed, but most have failed to

### AMD Risk Assessment

Figures 5A and 5B show ROC curves using Observer 1 and Observer 2 as reference standards, obtaining Az values of 0.948 and 0.954, respectively. Observer 2 reached an image sensitivity of 0.85 and an image specificity of 0.96, as shown in Figure 4, whereas Observer 1 obtained an image sensitivity of 0.84 and image specificity of 0.96 (Fig. 5). Table 5 shows the contingency table and kappa (κ) agreement between the observers and between the CAD system and the observers for AMD risk assessment. The threshold for the CAD system was set at the cutoff point that maximizes sensitivity + specificity.
achieve acceptable performances compared to human grad-
ers or are only able to give categorized outcome
values.

In addition to detection, accurate localization and segmen-
tation of drusen are very important to adequate quantification
of drusen load in an image. In contrast to other methods, where the performance analysis was carried out by pixel-to-
pixel comparison, we performed FROC analysis, stressing
the importance of a correct localization and segmentation of
individual lesions and providing higher statistical power than
conventional ROC analysis for this task.

With respect to quantification of the total drusen area, there
is high agreement between the observers and the proposed
CAD system (Fig. 4). The CAD system also showed similar
agreement with the observers independently of the camera
used for the acquisition. However, a more exhaustive analysis
should be made in order to evaluate the effect of the image
quality of manual and automatic drusen quantification. In a
previously proposed drusen quantification method, a slightly
higher ICC value was reported (ICC = 0.92) than the ground
truth based on the average grading of eight experts. However,
in that study, images with the highest variability among
observers were excluded from the study. This was the case
for five images, resulting in the exclusion of more than 20% of
the total dataset, which is likely to influence the outcome.

For the estimation of maximum druse diameter, agreement
between the CAD system and the observers was lower, with a
maximum ICC value of 0.69. However, the interobserver
agreement on this measurement also decreased. These lower
values might be explained by the fact that a correct druse
diameter depends on accurate druse delineation, which may be
hampered by several factors. For human observers, the main
problem lies in the analysis and classification of complex
morphological patterns that characterize drusen, whereas
the CAD system is impeded mostly by low image quality, poor
contrast, or neighboring artifacts.

In this study, we also examined AMD risk assessment, and
we showed that the CAD system performs as well as the
human observers (Fig. 4, Table 4). Images incorrectly classified
by the system in the low-risk stage corresponded mainly to
cases of disagreement between the observers (40% of
et al.\textsuperscript{50} developed an algorithm for identification of AMD with a presence or absence of disease instead of trying to separate high-risk from low-risk AMD patients, which is clinically more relevant. Zheng et al.\textsuperscript{50} developed an algorithm for identification of AMD with a sensitivity of 99.4\% and a specificity of 100\%. However, the authors compared their CAD system only to a single human observer, which can lead to false high performance.

In contrast to previously published CAD systems,\textsuperscript{25–27,29,31,32,42–46} our software performs drusen quantification independently of a fixed region of interest. With full image drusen detection, more information from the image is extracted which can be beneficial if our method would be deployed in clinical studies of AMD. For example, in studies of the cuticular drusen subtype of AMD, diagnosis is based on a typical pattern of innumerable small drusen on fluorescein angiography (FA), not only in the macular region but also in the peripheral retina.\textsuperscript{34,51} It would be very valuable to evaluate this drusen pattern to see if regions identified on FA were also detected by the CAD system on color images.

In our system, misclassification of candidates as true drusen often occurred due to reflections of the internal limiting membrane or because of the presence of non-AMD-related abnormalities. Adding better features to characterize these regions or including them as samples in the learning process of the CAD system might solve this problem in the future. Depending on their number and size, false-positive drusen detection might lead to incorrect AMD risk assessment. However, in our study, this did not occur very often. It is possible that these false-positive drusen have a relatively low probability of being a true druse, which is accounted for during computation of AMD risk. In addition, we did not consider pigmentary changes for automatic AMD risk assessment.

We are not aware of any implementation of AMD screening programs, but there have been studies evaluating cost effectiveness of such programs.\textsuperscript{52,53} However, the proposed programs are based on self-testing, whereas screening based on evaluation of color fundus images would be preferable.

Deployment of human graders in such a broad setting would be costly and time consuming, and implementation of an automatic detection system would circumvent these problems. The CAD system could, for example, be installed in opticians’ offices and be implemented in routine evaluation of elderly people. High-risk individuals would be selected on site and referred for further ophthalmologic evaluation.

In conclusion, we have developed and evaluated a machine learning system for identification of high-risk AMD patients. Our system allows for accurate detection and quantification of drusen location, area, and size, with a performance equal to human observers under stringent testing conditions. Implementation of our system allows for quick and reliable diagnosis of AMD in screening as well as in research programs. Additionally, there is a need for detailed phenotyping of large datasets in order to gain more insight into risk factors and disease mechanisms involved in AMD.\textsuperscript{34} With the use of an automatic detection system, identification of homogeneous AMD subgroups and genotype-phenotype correlations should be achievable in a broader context.\textsuperscript{25}

APPENDIX A

Druse Candidate Extraction
In this step, pixels that are potentially bright lesion pixels are extracted by convolving the green channel of the color fundus image with a group of Gaussian filters. These filters are based on Gaussian derivatives up to second order at different scales of information.30 A kNN classifier is then trained to classify every pixel in the image on the basis of the filter responses.35 No preprocessing of the image is needed previous to the druse candidate extraction step, such as suppression of luteal pigmentation.26,31,32 After classification, a pixel probability map is obtained that indicates the probability of each pixel to be part of a bright lesion. Neighboring pixels with similar probability were grouped into druse candidates. Algoritms that perform optic disc segmentation and vessel segmentation30 were also applied in order to remove candidates that overlapped with these anatomical landmarks and to use in further processing.

Druse Candidate Segmentation
In order to find the border of the drusen candidates, dynamic programming54 is applied around the local maxima of the calculated pixel probability map. During this process, the gradient magnitude of the Gaussian derivatives is used as cost function to guide the algorithm to the candidate borders.

Druse Candidate Classification
In order to determine whether a druse candidate is a true druse or not, a classification step using an LDA is performed.35 For each druse candidate, a total of 109 features based on color, intensity, contextual information, and shape are extracted (Table 6).30 These features exploit the different characteristics that the drusen show in color fundus images.

AMD Risk Assessment
To separate high-risk from low-risk patients, a weighted histogram of the calculated drusen probabilities in the image is created to encode drusen extension and size. The value $b_n$ of the histogram bin $n$ is defined as:

\[ b_n = \sum_{i \in L_n} p_i \]

where $p_i$ is the posterior probability of druse candidate $i$, and $L_n$ is the group of candidates whose size is $\tau n \leq d_i < \tau(n+1)$, in which $d_i$ is the size ($\mu$m) of candidate $i$. Terms $\tau$ and $n$ control the bin size and the histogram resolution, respectively, and values were chosen as $n = 0, \ldots, 36$ and $\tau = 10 \mu$m. The last bin ($n = 36$) takes all candidates with sizes $d_i > 360 \mu$m into account. A random forest (RF) classifier36 is then trained by using the histogram bins as features to distinguish high-risk patients.
