*Candida albicans* is the most common human fungal pathogen causing mucosal and systemic infections. However, human antifungal immunity remains poorly defined. Here by integrating transcriptional analysis and functional genomics, we identified *Candida*-specific host defence mechanisms in humans. *Candida* induced significant expression of genes from the type I interferon pathway in human peripheral blood mononuclear cells. This unexpectedly prominent role of type I interferon pathway in anti-*Candida* host defence was supported by additional evidence. Polymorphisms in type I interferon genes modulated *Candida*-induced cytokine production and were correlated with susceptibility to systemic candidiasis. In *in vitro* experiments, type I interferons skewed *Candida*-induced inflammation from a Th17 response towards a Th1 response. Patients with chronic mucocutaneous candidiasis displayed defective expression of genes in the type I interferon pathway. These findings indicate that the type I interferon pathway is a main signature of *Candida*-induced inflammation and has a crucial role in anti-*Candida* host defence in humans.

**C**<sub>andida albicans</sub> is a commensal microorganism that inhabits human skin and mucosa. *Candida* can be isolated from up to 70% of the general population at any given moment, and it is believed that all individuals have been colonized with *Candida* at a some point<sup>1</sup>. Although it is a commensal organism, *C. albicans* can also cause mucosal and systemic infections, especially in immunocompromised hosts<sup>2</sup>. Despite the availability of novel classes of antifungal agents (for example, azoles, echinocandins), mortality due to systemic candidiasis, the fourth most common form of sepsis<sup>3–5</sup>, reaches 37–44% (refs 3,6,7). In addition, vaginal and oral candidiasis can also occur in healthy or only mildly immunocompromised individuals<sup>8</sup>, with up to 5% of women in the general population suffering from recurrent vulvovaginal candidiasis<sup>9</sup>.

Despite the introduction of modern antifungal drugs and intensive care facilities, progress in improving the outcome of *Candida* infections in the last decade has been disappointing. Given this lack of progress, it is currently believed that only adjuvant immunotherapy will be able to further reduce the burden of morbidity and mortality caused by *C. albicans* infections<sup>10</sup>. Understanding the host defence pathways involved in candidiasis is therefore crucial for identifying novel targets for immunotherapy. To date, all investigations aimed at identifying antifungal host defence mechanisms in humans have relied on candidate-target approaches that are based on biologic plausibility of hypotheses extracted from in vitro or animal studies. Although this approach has been fruitful in confirming important pathways of antifungal defence, it has lacked the power to provide a hierarchy of the importance of these pathways, and to identify potentially novel and unexpected host defence mechanisms against *Candida*.

In the present study, we have taken an alternative, unbiased approach to this biological problem. Using a combination of transcriptional analysis and systems biology, we have stimulated human primary cells with the fungus, identifying *Candida*-specific transcription profiles in human immune cells. Although *C. albicans* induced the transcription of multiple inflammatory gene sets commonly stimulated by other inflammatory stimuli, it also specifically induced several additional gene sets, among which we identified an unexpectedly strong type I interferon (IFN) signature profile. We confirmed the importance of the type I IFN pathway for anti-*Candida* host defence in humans through immunological and genetic studies in both healthy volunteers and in patients with systemic candidiasis or suffering from chronic mucocutaneous candidiasis (CMC).

**Results**

*C. albicans* induces a type I IFN response. We measured genome-wide transcriptional profiles in peripheral blood mono-nuclear cells (PBMCs) from healthy volunteers upon stimulation with *C. albicans*, as well as with inflammatory stimuli unrelated to fungal pathogens: *Escherichia coli*-derived lipopolysaccharide (LPS), *Borrelia burgdorferi*, *Mycobacterium tuberculosis* (MTB) and RPMI culture medium as a control. Measurements were performed at 4 and 24 h. A total of 693 transcripts that showed >2-fold higher expression compared with corresponding RPMI stimulation were selected (Benjamini and Hochberg’s (BH)-adjusted *P*< 0.05). K-means analysis identified profile clusters that indicated shared and specific genes that were differentially expressed in response to each stimulus. We grouped shared genes in signatures representing common early response genes (clusters 1, 6, 14, 27), common late response genes (clusters 2, 3) and common inflammatory genes induced by all stimulations (clusters 9, 21, 25) (Fig. 1a and Supplementary Figs S1–S3).

More importantly, to identify a set of discriminatory features (from the 693 differentially expressed transcripts) that would be most informative of the state of *Candida* stimulation and could distinguish *Candida* stimulation from the other inflammatory stimuli, we utilized information gain (Kullback–Leibler divergence:relative entropy) feature selection, to reduce the dimensionality of the feature space<sup>11,12</sup>. We performed 10-fold cross-validation that stratifies the data into 10 random partitions in which each (in turn) is held out for testing and the remainder for training a Bayesian classifier. Class prediction was evaluated by computing the area under the receiver-operating characteristic curve, which assesses true- and false-positive rates. A 101-transcript (95-gene) *Candida*-response signature (Fig. 1b and Supplementary Table S1) was defined using this supervised learning approach for class prediction, achieving an area under the receiver–operating characteristic curve of 97.8%, which would indicate an excellent classifier performance with very high discriminative value. Principal component analysis of the *Candida*-response signature further demonstrated good class separation on the basis of *Candida* status and stimulation duration (Fig. 1c). As a set, the 101 features collectively identify expression signatures that are informative of *Candida* stimulation across the 4, 24-h or both time points that sufficiently distinguish *Candida* from the rest. Enrichment analysis for the 101 transcript *Candida*-response signature revealed a striking overrepresentation of the IFN signalling pathway (*P* = 3.8 × 10<sup>-3</sup>) (Fig. 1d and Supplementary Table S2). This set of genes was strongly induced at both 4 and 24 h of *Candida* stimulation and establishes a definitive *Candida*-responsive signature distinct from that observed with LPS, MTB or *Borrelia* stimulation.

**Type I IFN SNPs modulate susceptibility to candidemia.** To assess whether the type I IFN genes specifically induced by *C. albicans* in human leukocytes are indeed involved in antifungal host defence, we investigated whether common polymorphisms in a subset of these genes influence susceptibility to systemic *Candida* infections. From a cohort of 217 Caucasian patients with candidemia, well described elsewhere<sup>10,13</sup>, we had Immunochip genotyping data available and 11 genes of the 101-transcript (95-gene) data set were covered by the Immunochip array (Supplementary Table S3). We tested these 11 genes for association by taking immunochip data on 12,228 non-candidemia Caucasian healthy volunteers as controls<sup>14</sup>. Analysis of the loci associated with these 11 genes revealed significant association of genetic variation with susceptibility to systemic candidiasis in four regions: *CCL8* SNP 1kg_29697448 (*P* = 0.00069), *STAT1* SNP rs16833172 (*P* = 0.0042), *SP110* SNP rs3769845 (*P* = 0.012) and *PSMB8* SNP rs3198005 (*P* = 0.01) (Fig. 2a–d; Supplementary Figs S1–S3, clusters 10, 11, 20, 11, respectively) (Supplementary Table S3). After applying a stringent Bonferroni correction for multiple testing, the association between susceptibility to candidemia and *STAT1* and *CCL8* remained significant. This finding confirms that the *C. albicans*-specific genes we identified in our transcriptional arrays have an important role in host defence against systemic fungal infections. We also attempted to assess whether the polymorphisms in these genes also modified disease severity. However, only 51 patients fulfilled the criteria of severe candidiasis based on clinical scores and persistence of positive blood cultures, and this number was too low for allowing the identification of significant differences between genetic variation and disease severity (disseminated disease, persistent fungemia and mortality at 14 or 30 days) (data not shown).

**Type I IFN SNPs modulate Candida-induced cytokine responses.** In an additional approach to validate the role of the type I IFN pathway for host defence against *Candida*, we isolated...
PBMCs from an additional group of 74 healthy volunteers and stimulated the cells with the fungus. Genetic variation in 11 type I IFN pathway genes present on the Immunochip was correlated with \( C. \text{albicans} \)-induced release of tumour-necrosis factor-\( \alpha \) (TNF-\( \alpha \)), interleukin (IL)-1\( \beta \), IL-8, IL-6, IL-10, IFN-\( \gamma \) and IL-17. In contrast to other microbial stimuli such as LPS and MTB, \( C. \text{albicans} \) induced higher levels of TNF-\( \alpha \), IL-1\( \beta \) and IL-10 production, and lower levels of IL-8 and IL-6 in human PBMCs (Supplementary Fig. S4). The correlation of cytokine concentrations with genotypes at tag single nucleotide polymorphisms (SNPs) of \( C. \text{albicans} \)-induced IFN pathway genes revealed significant associations at \( IRF1 \) and \( STAT1 \) regions (Fig. 3a–d) in which \( IRF1 \) SNPs were associated with TNF-\( \alpha \) (\( P = 0.0028 \)) and IL-10 levels (\( P = 0.0024 \)), whereas \( STAT1 \) SNPs were associated with TNF-\( \alpha \) (\( P = 0.001 \)) and IL-6 levels (\( P = 0.0002 \)). Consistent with the specificity of the type I IFN pathway for \( C. \text{albicans} \) stimulation, the association was significant with cytokine levels induced by \( C. \text{albicans} \), but not by LPS or MTB stimulation (Supplementary Fig. S5).

**Type I IFNs skew cytokine responses from Th17 towards Th1.** To investigate the importance of type I IFN signalling in host defence against \( C. \text{albicans} \), PBMCs from healthy individuals were stimulated with heat-killed \( C. \text{albicans} \). In line with the transcriptional profile described above (Fig. 1), IFN-\( \beta \) could be detected in cell culture supernatants only after \( C. \text{albicans} \) stimulation. In contrast, neither live (Fig. 4a), nor heat-killed \( C. \text{albicans} \) induced any detectable IFN-\( \alpha \) production.
We next assessed the role of type I IFN pathways in the induction of cytokines by *C. albicans*. When PBMCs were stimulated with heat-killed *C. albicans* in the presence of an antibody against IFN-α/β/γ receptor 1 (IFNAR), IFNγ production was significantly lower compared with PBMCs stimulated in the presence of a control antibody. Blocking of IFNAR did not influence the production of the monocyte-derived cytokines IL-β or TNF-α (Fig. 4b). Conversely, adding IFN-α or IFN-β to *Candida*-stimulated cells increased IFN-γ production, while significantly decreasing IL-17 and IL-22 production (Fig. 4c). Together these data indicate that type I IFNs (in the context of infection, most likely IFN-β) modulate the immune reaction induced by *C. albicans*, skewing host defence towards a Th1 response.

**STAT1 mutations cause reduced expression of type I IFN genes.** Patients with autosomal-dominant CMC have increased susceptibility to mucosal fungal infections and often carry gain-of-function mutations in *STAT1* (refs 15,16), which lead to *STAT1* hyperphosphorylation, that in turn likely makes STAT1 unavailable for forming heterodimers with other STAT molecules17. In co-cultures of dendritic cells (DCs) and T cells from CMC patients, this led to defective Th1 and Th17 responses (Supplementary Fig. S6). To validate the role of *Candida*-specific genes in human antifungal mucosal defence, we assessed the expression of these genes in cells from CMC patients. PBMCs from healthy controls and CMC patients were stimulated with RPMI, *E. coli*-derived LPS, heat-killed *C. albicans*, or heat-killed MTB. The expression of type I IFN pathway genes (including
were measured in cell culture supernatants using ELISA. (c) A total of $5 \times 10^5$ PBMC in a volume of 200 µl were stimulated for 2 and 7 days, with heat-killed $C. albicans (1 \times 10^6 \text{ ml}^{-1})$, in the absence or presence of IFN-α or IFN-β, in duplo. When cells were cultured for 7 days, this was done in the presence of 10% human-pooled serum. IFN-γ, IL-17 and IL-22 were measured in cell culture supernatants using ELISA. (a-c) After stimulation, supernatants were pooled and stored at $-20^\circ\text{C}$ until further assayed. Data were analysed using the Wilcoxon-signed rank test. Data are presented as mean $\pm$ s.e.m.

**Discussion**

The last decade has witnessed a significant increase in knowledge related to the mechanisms involved in antifungal host defence. However, most of this knowledge is based on *in vitro* and animal studies; these studies led to hypotheses to be tested in human systems, leading to a somewhat biased view of human immunity against fungi. In the present study we have used a different approach based exclusively on complementary human studies: transcriptomics analysis in human primary cells, correlation of genetic variability and antifungal immunity in healthy volunteers (functional genomics), case–control association studies in patients with disseminated *C. albicans* infections, and assessment of antifungal immunity in CMC patients.

In our initial approach, we designed a hypotheses-generating set of experiments by assessing the transcriptional profile induced in circulating primary leukocytes by *C. albicans*. Human primary PBMCs were stimulated either with *C. albicans* or with other inflammatory stimuli. Pathway analysis of the genes induced by *Candida* indicated two broad categories: (i) a first set of genes that was strongly induced and shared by both *C. albicans* and other inflammatory stimuli (LPS, MTB or *B. burgdorferi*), constituted expected pathways involved in inflammation and innate immunity, many of which have important roles in antifungal immunity, and (ii) a feature set comprising an expression signature of 101 transcripts (95 genes) that distinguishes the *Candida*-specific response and is characterized by a strikingly strong and unanticipated type I IFN response.

**Figure 4 | Type I IFNs skew cytokine production from a Th1 towards a Th17 response.** (a) $5 \times 10^5$ PBMC in a volume of 200 µl were stimulated for 7 days, in the presence of 10% human pooled serum, with live *C. albicans* ($1 \times 10^6 \text{ ml}^{-1}$), in duplo. IFN-α and IFN-β were measured in cell culture supernatants using enzyme-linked immunosorbent assay (ELISA). (b) $5 \times 10^5$ PBMC in a volume of 200 µl were stimulated for 1 and 2 days, with heat-killed *C. albicans* ($1 \times 10^6 \text{ ml}^{-1}$), in the absence or presence of anti-IFN-α/βR2, in duplo. IFN-γ, IL-1β and TNF-α were measured in cell culture supernatants using ELISA. (c) A total of $5 \times 10^5$ PBMC in a volume of 200 µl were stimulated for 2 and 7 days, with heat-killed *C. albicans* ($1 \times 10^6 \text{ ml}^{-1}$), in the absence or presence of IFN-α or IFN-β, in duplo. When cells were cultured for 7 days, this was done in the presence of 10% human-pooled serum. IFN-γ, IL-17 and IL-22 were measured in cell culture supernatants using ELISA. (a-c) After stimulation, supernatants were pooled and stored at $-20^\circ\text{C}$ until further assayed. Data were analysed using the Wilcoxon-signed rank test. Data are presented as mean $\pm$ s.e.m.
Because the identification of the type I IFN pathway as the most prominent Candida-specific transcriptional signature was surprising, we initiated a series of studies to confirm this finding. First, we assessed whether genetic polymorphisms in several of the genes identified in the Candida-specific data set influenced susceptibility to systemic Candida infections. In a cohort of patients with candidemia that were genotyped using the Immunochip platform (Illumina\textsuperscript{14}), on which 11 genes of the Candida susceptibility to systemic infections. In a cohort of patients with candidemia that were genotyped using the Immunochip platform (Illumina\textsuperscript{14}), on which 11 genes of the Candida-specific data set were covered, we identified significant association of genetic variation with susceptibility to candidiasis in four of these genes: CCL8 locus, STAT1, SP110 locus and PSMB8 locus. This finding confirms that genes from the 101 Candida-specific data set influence susceptibility to systemic fungal infections.

Second, the role of the type I IFN pathway for the anti-Candida immune response was subsequently validated in a study in which PBMCs isolated from a group of healthy volunteers were stimulated with the fungus. Genetic variation in the 11 type I IFN pathway genes present on the Immunochip was correlated with C. albicans-induced cytokine production. The correlation of cytokine concentrations with genotypes at tag SNPs of Candida-induced IFN pathway genes revealed significant associations at IRF1 and STAT1 regions, both crucial components of type I IFN pathway. We cannot exclude, however, that the effect of these polymorphisms on TNF-\(\alpha\) production are exerted through type II IFNs; IFN-\(\gamma\) is stimulated by type I IFNs\textsuperscript{19}, and is known to induce TNF-\(\alpha\) production\textsuperscript{20}. These data support the hypothesis of the specificity of the type I IFN pathway for Candida stimulation, as this association was significant only for cytokine production induced by Candida, but not by other stimuli.

Third, we performed classical immunological studies to assess the role of type I IFNs for Candida-induced immune responses, and we demonstrated that type I IFNs induced by Candida modulate Th1/Th17 cytokine profiles; IFN-\(\gamma\) and IFN-\(\beta\) increased IFN-\(\gamma\) production, while decreasing IL-17 production. Moschen et al.\textsuperscript{21} previously demonstrated that type I IFNs decrease IL-17 production in vitro and in vivo. TNF-\(\alpha\) production did not seem to be influenced by blocking the IFNAR, suggesting that genetic effects in STAT1 exert their effect on TNF-\(\alpha\) production either through direct intracellular pathways, or indirectly through IFN-\(\gamma\). Interestingly, C. albicans seems to induce only IFN-\(\beta\), rather than IFN-\(\gamma\), consistent with earlier studies in mice\textsuperscript{22,23}.

Finally, using both quantitative PCR and RNA sequencing analysis, we demonstrated that the expression of type I IFN pathway-induced genes was defective in CMC patients harbouring a gain-of-function mutation in STAT1 (ref. 15). These mutations lead to increased STAT1 phosphorylation and IFN-\(\gamma\) signalling. Liu et al.\textsuperscript{16} demonstrated increased STAT1 phosphorylation in response to IFN-\(\gamma\) stimulation in U3C cells transfected with mutated STAT1. They hypothesize that IFN-targeted genes can lead to decreased IL-17 production. However, freshly isolated PBMC from CMC patients do not produce any IFN-\(\gamma\) in response to C. albicans stimulation\textsuperscript{15}. Therefore, it is more likely that the inability of mutated STAT1 to form heterodimers with STAT3 and STAT4 causes defective Th1/
Figure 6 | Heatmap of response of CMC patients and controls to *C. albicans* in vitro stimulation. In this analysis the standardized fold change gene expression in stimulated versus unstimulated cells was calculated. The scale of this heatmap is given as standardized log2 fold change with a range from −1.8 (blue) to +1.8 (red).
Th17 responses, which are likely to represent the main immunological defect in this disease. Additional defects in the expression of type I IFN-induced genes, as shown here, may also contribute to the increased susceptibility to mucosal fungal infections. Whether this is truly caused by a defect in STAT1-STAT2 heterodimerization remains to be demonstrated.

Taken together, these complementary studies represent a compelling body of evidence that the type I IFN pathway is an important component of the immune response during infections with C. albicans in humans. Moreover, the data presented here are supported by emerging information from murine studies. For example, Bourgeois et al. and Biondo et al. have reported that mouse conventional DCs produce IFN-β upon stimulation with Candida spp. and have proposed a role for MyD88, TLR7 and TLR9 in this induction. On the other hand, these results are relatively surprising, as no earlier study has reported a role for type I IFNs in human antifungal host defence. In this respect, primary immunodeficiencies in type I IFN pathway are mainly associated with viral, rather than fungal, infections. Therefore, our data indicate that type I IFN defects determine an increase susceptibility risk for fungal infections, as demonstrated here by the association with candidemia in risk groups, rather than an overt immunodeficiency associated with severe fungal infections.

The precise effect of type I IFNs for anti-Candida host defence is still being debated. One study in type I IFNAR knockout mice suggested a deleterious role for this pathway, whereas another study reported that IFNAR–/– mice die from their inability to control fungal growth. Although type I IFNs have an important role in the immune response against viral infections, they seem to be deleterious in bacterial infections. In humans with Candida infections, the role of type I IFNs is not yet settled, although the defects seen in type I IFN gene expression in CMC patients, the susceptibility to candidemia by STAT1 polymorphisms, and the potentiation of Th1 responses by type I IFNs, all suggest a beneficial effect of the type I IFN pathway in human antifungal host defence.

Although viruses have long been known to induce type I IFN production, other microorganisms have been recently reported to induce this pathway. MTB stimulation induces the expression of IFNB and IFNA1 in human macrophages and in murine bone marrow-derived macrophages. Type I IFNs are required for caspase-1 activation during Francisella tularensis infection and Listeria monocytogenes induces the transcription of IFNB in macrophages. However, the complete transcriptional profile of the type I IFN pathway performed here shows important differences from the type I IFN profile induced by MTB and is significantly more pronounced for Candida than for MTB (Supplementary Fig. S4). Interestingly, the strong induction of type I IFN pathway genes by Candida may explain the well-known, yet unexplained, beneficial effects of injecting Candida-derived extracts for the treatment of warts in patients.

In summary, this work presents complementary arguments from several studies to propose that the type I IFN pathway has an important role in the immune responses to the fungal pathogen C. albicans in humans. The cross-validation between these approaches supports the value of this systems biology approach, combining transcriptomics with functional genomics and immunological data. Using this approach, we have confirmed the role of pathways known to be involved in antifungal host defence (for example, common inflammatory pathways and the Th1/Th17 pathways) and we have identified a novel pathway (the type I IFN pathway). It is expected that this knowledge will have an important contribution in devising novel immunotherapeutic strategies for fungal infections, as well as influencing decision-making for vaccine design.

Methods

Study population. For assessing the transcriptome and the cytokine production capacity, blood was collected after written informed consent from healthy volunteers. Adult patients with candidemia were enrolled after informed consent (or waiver as approved by the Institutional Review Board) at the Duke University Hospital (DUMC, Durham, North Carolina, USA) and Radboud University Nijmegen Medical Centre (RUNMC, Nijmegen, The Netherlands). The study was approved by the Institutional Review Boards at each study centre, and enrolment occurred between January 2003 and January 2009 (ref. 34). The study was performed in accordance with the declaration of Helsinki. In addition, blood was collected from two patients with CMC (on two different occasions) and eight healthy controls to investigate the induction of IFN genes by Candida. After informed consent was given, blood was collected by venipuncture into 10 ml EDTA syringes (Monocyte, s-Hertogenbosch, The Netherlands).

PBMC isolation. Separation and stimulation of PBMCs was performed as described previously. Briefly, the PBMC fraction was obtained by density centrifugation of diluted blood (1 part blood to 1 part pyrogen-free saline) over ficoll-Paque (Pharmacia Biotech, Uppsala, Sweden). PBMCs were washed twice in saline and suspended in culture medium. The cells were counted in a haemocytometer and their number was adjusted to 5 × 10^5 ml^-1.

Cell stimulation. For the transcriptome analysis, cells were stimulated for 4 or 24 h with RPMI, heat-killed B. burgdorferi (2 × 10^6 ml^-1), C. albicans (UC 820) (1 × 10^6 ml^-1), C. glabrata (4 × 10^6 ml^-1) or E. coli-derived LPS (10 ng ml^-1). To correlate cytokine production to SNPs in the type I IFN pathway, 5 × 10^5 PBMCs from healthy volunteers were stimulated with heat-killed C. albicans (1 × 10^6 ml^-1) for 24 h. To investigate the effect of type I IFNs on cytokine production, 5 × 10^5 PBMCs were stimulated with heat-killed C. albicans (1 × 10^6 ml^-1) in the absence or presence of IFN-α/β (1 × 10^6 U ml^-1) (IntronA, SP Labo N.V., Heist-op-den-Berg, Belgium), IFN-β (10 ng ml^-1) or anti-IFNAR (100 ng ml^-1) (21385-1, PBL Interferon Source, Piscataway, USA). To assess the development of Th1 and Th17 cells, a total of 1 × 10^6 mononuclear cells were added to 96-well flat-bottom plates (Greiner). Subsequently, the monocytes within the PBMC pool were differentiated towards DCs by addition of IL-4 (50 ng ml^-1) (R&D Systems), GM-CSF (50 ng ml^-1), IL-6, IL-8, IL-10, IFN-γ (Sanquin, Amsterdam, the Netherlands) and IFN-α, IFN-β (PBL Interferon Source, Piscataway, USA) and 10% human serum for 7 days. After every second day, half of the medium was replaced by fresh DC differentiation medium. At day 7 of the culture, cells were stimulated with 1 × 10^6 Candida conidia for another 6 days.

Transcriptome analysis. Global gene expression was profiled using Illumina Human HT-12 Expression BeadChip according to manufacturer’s instructions. Image analysis, bead-level processing and quantile normalization of array data were performed using the Illumina LIMS platform, BeadStudio. A gene-wise linear model was fitted to the data and was performed in R programming language (http://www.r-project.org/), utilizing functions from Linear Models for Microarray Data. For each probe, a moderated t-statistic (with s.e. moderated across genes) was computed using a Bayesian model. The association was adjusted to control the false discovery rate in multiple testing, using the BH method. For each transcript, Signal-to-Noise ratios (SNR) were computed for each infection or stimulus group relative to the untreated (RPMI) control group. The expression SNR profiles of transcripts identified as differentially expressed (BH-adjusted P < 0.05 and fold-change > 2 × ) were clustered using the k-means algorithm. We performed feature (attribute) selection on differentially expressed transcripts using Information Gain (Kullback-Leibler divergence or relative entropy) to identify discriminatory features or transcripts that are most informative of the state of infection or stimulation. The accuracy of class prediction using a Java implementation of a naive Bayes classifier incorporating these features was evaluated using 10-fold cross-validation.

Cytokine measurements. The concentration of IL-1β, IL-17, IL-22, TNF-α (R&D Systems, Abingdon, UK), IL-6, IL-8, IL-10, IFN-γ (Sanquin, Amsterdam, the Netherlands) and IFN-α, IFN-β (PBL Interferon Source, Piscataway, USA) was measured in cell culture supernatants using enzyme-linked immunosorbent assay according to the instructions of the manufacturer.

SNP selection. DNA was isolated using the Gentra Pure Gene Blood kit (Quiagen, Netherlands) and IFN-α, IFN-β (PBL Interferon Source, Piscataway, USA) was measured in cell culture supernatants using enzyme-linked immunosorbent assay according to the instructions of the manufacturer.
Statistical analysis. Analyses were performed using PLINKv1.07 (ref 45, 46). We performed Multidimensional scaling (MDS) analysis to reveal genetic background of cases and controls in Candidemia cohort (Supplementary Fig. 58). The association between tag-SNPs and Candidemia susceptibility was tested by logistic regression with the first four components from MDS analysis as covariates. The correlation between cytokine levels and genotypes was tested by Wilcoxon rank sum test using R. P < 0.05 was considered significant.

Real-time PCR. Two million freshly isolated PBMCs were incubated with various stimuli as described above. After 24 h of incubation at 37 °C, total RNA was extracted in 800 µl of DenaZol Reagent (Invitrogen, Breda, The Netherlands). Isolated RNA was reverse- transcribed into complementary DNA using oligo(dT) primers and MMLV reverse transcriptase. PCR was performed using a 7300 Real-Time PCR system (Applied Biosystems, Lennik, Belgium). Primer sequences for human IFN-
