Abstract

1 Two fundamental factors affecting the speed of spoken word production are lexical frequency and
2
3
4 sentential constraint, but little is known about their timing and electrophysiological basis. In the
5
6 present study, we investigated event-related potentials (ERPs) and oscillatory brain responses
7
8 induced by these factors, using a task in which participants named pictures after reading sentences.
9
10 Sentence contexts were either constraining or nonconstraining towards the final word, which was
11
12 presented as a picture. Picture names varied in their frequency of occurrence in the language.
13
14 Naming latencies and electrophysiological responses were examined as a function of context and
15
16 lexical frequency. Lexical frequency is an index of our cumulative learning experience with words,
17
18 so lexical-frequency effects most likely reflect access to memory representations for words. Pictures
19
20 were named faster with constraining than nonconstraining contexts. Associated with this effect,
21
22 starting around 400 ms pre-picture presentation, oscillatory power between 8-30 Hz was lower for
23
24 constraining relative to nonconstraining contexts. Furthermore, pictures were named faster with
25
26 high-frequency than low-frequency names, but only for nonconstraining contexts, suggesting
27
28 differential ease of memory access as a function of sentential context. Associated with the lexical-
29
30 frequency effect, starting around 500 ms pre-picture presentation, oscillatory power between 4-10
31
32 Hz was higher for high-frequency than for low-frequency names, but only for constraining contexts.
33
34 Our results characterise electrophysiological responses associated with lexical frequency and
35
36 sentential constraint in spoken word production, and point to new avenues for studying these
37
38 fundamental factors in language production.

1. Introduction

1 Speaking is one of our most highly exercised psychomotor skills (Levelt, 1989). Seemingly simple
2 and effortless, the production of language relies not only on fast and accurate linguistic processes,
3
4 such as the access of concepts and lexical representations in long-term memory (Indefrey & Levelt,
5
6 such as the access of concepts and lexical representations in long-term memory (Indefrey & Levelt,
7
8 2004; Levelt, Roelofs, & Meyer, 1999), but also on precise motor preparation and execution
9
10 (Hickok, 2012). Although psycholinguistic models have provided a detailed description of the
11
12 cognitive architecture underlying language production (e.g., Caramazza, 1997; Dell, 1986; Levelt,
13
14 1989; Levelt et al., 1999; Roelofs, 1992, 1997), only recently electrophysiological markers of the
15
16 postulated cognitive processes have been explored (e.g., Aristei, Melinger, & Abdel-Rahman, 2011;
17
18 Eulitz, Hauk, & Cohen, 2000; Strijkers, Costa, & Thierry, 2010; Strijkers, Holcomb, & Costa, 2011;
19
20 see for review Ganushchak, Christoffels, & Schiller, 2011). In the present study, we examined
21
22 electrophysiological brain responses that are induced by two fundamental factors known to affect
23
24 the planning of spoken words: lexical frequency and sentential constraint (e.g., Griffin & Bock,
25
26 1998; Levelt, 1989).

27
28
29
30
31
32
33 Studies investigating lexical memory access in word production have made extensive use of
34
35 the picture-naming paradigm. This line of investigation builds on the following two ideas: (1) the
36
37 picture represents the concept to be expressed, and (2) producing the picture name requires access
38
39 to lexical memory (i.e., lemmas and word forms, e.g., Levelt et al., 1999). A typical finding in
40
41 picture-naming studies is that pictures whose names occur more frequently in the language (e.g.,
42
43 ‘house’ or ‘dog’) are named more quickly than pictures whose names occur less often in the
44
45 language (e.g., ‘spear’ or ‘globe’), a finding known as the *lexical-frequency effect* (e.g., Jescheniak
46
47 & Levelt, 1994; Oldfield & Wingfield, 1965). Since word frequency is an index of our cumulative
48
49 learning experience with words, the lexical-frequency effect is an important marker of long-term
50
51 memory processes and likely reflects the access of lexical memory representations (e.g., Almeida,
52
53 Finkbeiner, Knobel, & Caramazza, 2007; Jescheniak & Levelt, 1994; Kittredge, Dell, Verkuilen, &
54
55 Schwartz, 2008; Monaco, Abbott, & Kahana, 2007; Ullman, 2001). Lexical access is assumed to
56

64
65

1 consist of lexical selection and word-form encoding, which is further divided into morphological,
2 phonological, and phonetic encoding (Levelt et al., 1999). All of these stages have been shown to be
3 sensitive to frequency (e.g., Cholin, Dell, & Levelt, 2011; Jescheniak & Levelt, 1994; Piai, Roelofs,
4 & van der Meij, 2012; Roelofs, 1998; Strijkers et al., 2010). Lexical access takes place between
5 about 200 ms post picture-onset and about 145 ms before articulation onset (Indefrey, 2011;
6 Indefrey & Levelt, 2004).

Everyday language production, however, usually involves sentences. The conceptual content of the message to be expressed (i.e., the semantic context) guides the access to memory and the activation of associated lexical candidates (e.g., Griffin & Bock, 1998; Levelt, 1989; Levelt et al., 1999). Contextual cues constrain possible word candidates, thereby modulating the ease of lexical access and word production (Griffin & Bock, 1998). Sentential constraint is a major determinant of fluency in spontaneous speech production (Levelt, 1989).

In the present study, participants read sentences that were either contextually constraining towards one final word (e.g., ‘During the camping vacation, he was rarely in the’) or not (e.g., ‘During the day, he was rarely in the’). The final word of the sentence (‘tent’) was presented as a picture, which participants had to name. The lexical-frequency range of the picture names was varied (cf. Griffin & Bock, 1998). In short, sentential constraint and lexical frequency were manipulated in order to investigate the electrophysiological signatures of these factors in spoken word production. Ideally, effects of lexical frequency and sentential constraint are assessed in spontaneous speech, but this is still no option for language production research. Griffin and Bock (1998) stated, “Clearly, one cannot directly assess either the redundancy of message specifications for word selection or the onset of word-production processes in spontaneous speech. Hence, the task used in this study consisted of naming pictures which were preceded by sentence frames. It thereby combined an estimate of the onset of processing for a particular picture name with a quantifiable manipulation of contextual constraint. The weakness of the task is that the sentence contexts were read by participants rather than being generated by them. Although reading sentence frames differs

1 from generating messages, the product of comprehension should be similar to the conceptual
2 representations that speakers normally develop.” (p. 329).

3
4 Using this paradigm and measuring picture-naming response time (RT), Griffin and Bock
5 (1998) observed that pictures following a constraining context were named more quickly than
6 pictures following a nonconstraining context (for other studies using a similar task, see e.g.,
7
8
9
10
11 Badecker, Miozzo, & Zanuttini, 1995; Blom, & Vasić, 2011; Caramazza, & Hillis, 1989; Gollan et
12 al., 2011). Moreover, it was found that the lexical-frequency effect, commonly found with standard
13 picture naming (e.g., Oldfield & Wingfield, 1965), was only present in the naming latencies for
14 pictures following nonconstraining contexts, but absent for pictures following constraining
15 contexts. According to Griffin and Bock (1998), the activation of word-form representations in
16 memory follows a logistic function with high-frequency words having a higher resting level of
17 activation than low-frequency words. Sentential constraint is assumed to affect lexical (i.e., lemma)
18 selection, which is supposed to have a bigger impact on low-frequency than high-frequency words
19 because of the logistic activation of word forms. However, since naming latencies were the only
20 measure in that study, no information could be obtained about processes that occurred before the
21 picture was presented. In particular, it is unclear whether the interaction between lexical frequency
22 and sentential constraint occurred after picture presentation onset (Griffin & Bock, 1998) or already
23 before it. That is, the narrower context may have given lexical access a head start (i.e., access may
24 have started earlier in time, possibly already before picture onset) rather than affecting activation
25 levels of word forms after picture onset, as Griffin and Bock (1998) assumed. In the present study,
26 we investigated the effects of lexical frequency and sentential constraint on spoken word production
27 using the electroencephalogram (EEG), which allows us to investigate cognitive processes as they
28 unfold in time, revealing whether or not effects occur already before picture presentation onset.

54

55 Electrophysiological studies of language production have mainly focused on single-word
56 production using event-related potentials (ERPs, see for a recent review Ganushchak et al., 2011).
57
58 In contrast, in the present study, we focus on brain oscillations. Oscillations are a common type of
59
60
61
62
63
64
65

activity generated by neuronal populations (Buzsáki, 2006). Depending on the size of these populations and their degree of synchronisation, this neuronal activity can be recorded with EEG (Nunez & Srinivasan, 2006). This oscillatory activity is typically categorised into different frequency bands. Different cognitive functions have been associated with frequency-specific changes in oscillatory power (e.g., Engel & Fries, 2010; Hanslmayr, Staudigl, & Fellner, 2012; Jensen & Mazaheri, 2010; Khader & Rösler, 2011; Van Ede, de Lange, Jensen, & Maris, 2011).

Very little is known about oscillations in language production, especially with overt vocal responses (Ewald et al., 2012; Laaksonen, Kujala, Hultén, Liljeström, & Salmelin, 2012; Piai, Roelofs, & van der Meij, 2012; Piai, Roelofs, Jensen, Schoffelen, & Bonnefond, 2013). The few studies that did examine oscillations addressed diverse questions, using different paradigms and experimental manipulations. Therefore, no clear pattern has yet emerged characterising the oscillatory components associated with cognitive processes underlying language production.

Importantly, it has been shown that ERPs and oscillations can be complementary in the type of information they provide (e.g., Bastiaansen & Hagoort, 2003; Chen et al., 2012; Davidson & Indefrey, 2007; Donner & Siegel, 2011; Laaksonen et al., 2012). Yet, at present, almost all existing knowledge of the electrophysiology of language production is based on ERPs only (e.g., Aristei et al. 2011; Eulitz et al. 2000; Laganaro et al., 2009; Laganaro, Valente, & Perret, 2012; Strijkers et al. 2010, 2011; see for review Ganushchak et al. 2011). A characterisation of oscillatory activity has been fruitful in other cognitive domains, such as memory and motor control (see for reviews Engel, Fries, & Singer, 2001; Schroeder & Lakatos, 2009; Uhlhaas, Roux, Rodriguez, Rotarska-Jagiela, & Singer, 2010). By characterising the oscillatory activity underlying spoken word production, language production can be understood in a broader context of how cognitive processes are implemented in the brain, possibly providing ways to link findings from the language production literature with other domains of cognition.

In other tasks not involving language production, oscillatory brain responses have been better identified and some of these findings are relevant for the present study (i.e., language

comprehension, long-term memory access, and motor preparation). In particular, theta-band (4-8 Hz) activity has often been observed in relation to memory processes (e.g., Jacobs, Hwang, Curran, Kahana, 2006; Khader & Rösler, 2011; see for reviews Düzel, Penny, & Burgess, 2010; Klimesch, 1999; Nyhus & Curran, 2010), also involving the retrieval of lexical-semantic information during language comprehension (e.g., Bastiaansen et al. 2005, 2008). Oscillations in the alpha band (8-15 Hz) have been associated with a variety of cognitive processes, including semantic processing and memory (e.g., Hanslmayr et al. 2012; Klimesch, 1997; Klimesch, Doppelmayr, Pachinger, & Russegger, 1997; Röhm et al. 2001; see for a review Klimesch, 1999). However, in language comprehension, the involvement of alpha-band activity is less clear (e.g., Bastiaansen, van der Linden, Ter Keurs, Dijkstra, & Hagoort, 2005; Bastiaansen, Oostenveld, Jensen, & Hagoort, 2008; Röhm, Klimesch, Haider, & Doppelmayr, 2001; Willems, Oostenveld, & Hagoort, 2008; but see Mellem, Bastiaansen, Pilgrim, Medvedev, & Friedman, 2012). Finally, over the broader frequency range 8-30 Hz (encompassing both the 8-15 Hz alpha and the 15-30 Hz beta band), decreases in oscillatory power are reliably observed in relation to motor preparation and execution (e.g., Alegre et al., 2004; McFarland, Miner, Vaughan, & Wolpaw, 2000; Neuper, Wörtz, & Pfurtscheller, 2006, see for a review Cheyne, 2012), although they are not restricted to the motor system (Van Ede et al. 2011; Van Ede, de Lange, & Maris, 2012).

Our expectations for the present study were as follows. Regarding the behavioural responses, pictures in constraining contexts should be named more quickly than in nonconstraining contexts (Griffin & Bock, 1998). Moreover, in a nonconstraining context, participants cannot know in advance which picture will be presented. As a consequence, the picture name has to be retrieved from memory upon picture presentation, leading to a lexical-frequency effect in the naming latencies. In contrast, in a constraining context, participants are likely to predict the final word of the sentence (e.g., Dikker & Pykkänen, 2012), which is the picture they have to name. Presumably, they can already start the access of the picture name before the picture is presented. Therefore, we expected that the lexical-frequency effect in the naming latencies would be much smaller as

1 compared to the lexical-frequency effect in nonconstraining context sentences, replicating Griffin
2 and Bock (1998). Regarding the neuronal data, we expected lexical access to be indexed by
3 modulations in the theta or the alpha band, and therefore we predicted an effect of lexical frequency
4 on oscillatory power in these frequency bands. In particular, with a constraining context, in which
5 the lexical item can already be retrieved prior to picture presentation, the power modulations should
6 be observed before the picture is encountered (contrary to the assumption of Griffin & Bock, 1998).
7
8 Furthermore, when the lexical item is retrieved, its articulatory programme can also be prepared.
9
10 Since we expected motor preparation for speaking to be indexed by modulations in the alpha and
11 the beta band, we predicted an effect of contextual constraint (constraining versus nonconstraining
12 sentential context) on oscillatory power in these frequency bands.

23 **2. Method**

24 **2.1. Participants**

25
26 Seventeen native speakers of Dutch (8 male), all young adults, voluntarily participated in the
27 experiment for monetary compensation or for course credits. The datasets of two female
28 participants were not analysed due to poor blinking-speech coordination (i.e., the preparation to
29 speak was often accompanied by eye blinks), resulting in the loss of a large number of trials. Thus,
30 the complete dataset analysed and reported below comprised 15 participants. All participants were
31 right-handed, with normal or corrected-to-normal vision, and no history of neurological or language
32 deficits. Participants gave written consent after they were completely informed about the nature of
33 the study. The experiment was approved by the Ethics Committee for Behavioural Research of the
34 Social Sciences Faculty at Radboud University Nijmegen and followed the Declaration of Helsinki
35 (World Medical Association 1964, 2008).

52 **2.2. Materials**

53
54 One hundred and thirty line drawings of common objects were taken from the picture database of
55 the International Picture-Naming Project (Szekely et al., 2004). For each picture, two sets of
56 sentences were constructed for which the picture names were the last word of the sentences. In one
57
58
59
60
61
62
63
64
65

1 set, sentences were constructed such that the picture name was highly expected (constraining
2 context), whereas in the other set, no word was expected as the final word of the sentence
3
4 (nonconstraining context). There was no significant difference in sentence length between
5
6 conditions (mean number of words, constraining: 8.36, nonconstraining: 8.29; range: 6-13), $p =$
7
8 .677. Where possible, the sentences associated with the same target picture differed only in a few
9
10 words between conditions. In 74% of the sentences, a function word (a definite or indefinite article,
11
12 or a possessive pronoun) preceded the target picture name in the sentence. In the remaining
13
14 sentences, the word preceding the picture name was always an adjective, and care was taken that the
15
16 adjective used was either the same across the two sentences, or matched for frequency and number
17
18 of letters. The materials can be obtained on request.
19
20
21

22 **2.2.1. Pre-test of the sentence frames**

23
24 To verify that the sentences in the constraining and nonconstraining contexts differed in the degree
25
26 of expectancy for the final word (i.e., *cloze* probability; Taylor, 1953), a pre-test was conducted with
27
28 28 native speakers of Dutch (5 male). From the 260 sentences, we constructed two main lists, each
29
30 containing 65 sentences from each context condition. All sentences were presented up to, but
31
32 excluding, the last word of the sentence, which was the picture name. Participants received the
33
34 sentences via e-mail and were instructed to read the sentences one at a time and to provide three
35
36 completions (nouns) for each incomplete sentence. Two types of cloze probability were derived
37
38 (Griffin & Bock, 1998). The first-response probability was calculated based on the proportion of
39
40 participants who used the target picture-name as their first completion. The overall probability was
41
42 calculated as the proportion of participants who used the target picture-name as one of their
43
44 completions. Four pictures were excluded from the materials because the constraining sentences
45
46 associated with them had low cloze probability. The mean cloze probabilities of the remaining 126
47
48 pictures for the constraining and nonconstraining contexts are shown in Table 1. The sentences in
49
50 the nonconstraining condition did not have a high-cloze probability for any word.
51
52
53
54
55
56
57
58

59 **2.2.2. Lexical-frequency analysis**

60
61
62
63
64
65

To examine the effect of lexical frequency, we split the materials into a lower and a higher frequency set of picture names. For that, the log lemma frequency of the picture names was retrieved from CELEX (Baayen et al., 1993). Next, by taking the median log lexical frequency of all picture names (3.1 per million), they were split into a low (mean log frequency = 2.3 per million) and a high (mean log frequency = 4.3 per million) frequency conditions, on which subsequent analyses were conducted. Two measures of phonological complexity were determined: picture-name length in number of phonemes and the presence of consonant clusters. Words in the high- and low-frequency conditions did not differ in the proportion of consonant clusters (initial word-position: 27% and 14%; middle position: 0% and 3%; final position: 17% and 8% respectively; all p s > .08), but they were on average half a phoneme longer in the low-frequency than in the high-frequency condition, $p = .019$ (see Supplement for additional analyses). Name agreement measures were obtained for 120 of our 126 pictures from Severens, Van Lommel, Ratinckx, & Hartsuiker (2005). For the remaining six pictures, 15 young Dutch adults were asked to name the pictures using one word. The number of names given to the pictures and their H -statistic were calculated following Severens et al. Pictures in the high- and low-frequency conditions did not differ in the number of names given (on average 2.9 and 2.8, respectively, $p = .589$), nor in the H -statistic (on average .68 and .64, respectively, $t(124) < 1$). To evaluate whether the recognition of the experimental pictures was independent of the lexical frequency of their names, a picture recognition task was used (e.g., Piai et al., 2012). Twelve native speakers of Dutch (1 male), none of which took part in the experiment proper, performed the picture recognition task. In addition to the experimental pictures, 126 filler pictures were selected from the same picture gallery. Participants' task was to indicate with a button press whether a presented written word and a presented object referred to the same entity (right button) or not (left button). For the experimental pictures, the word and the picture always referred to the same entity; the filler pictures were always preceded by a different word. All 252 trials were randomly presented with one unique randomisation per participant. A trial started with the presentation of a written word in the centre of the screen for 500

ms, followed by a black screen for 500 ms, followed by a picture presented in the centre of the screen for 1 s. Only the response times (RTs) of the experimental pictures with correct verification were analysed (mean error percentage = 4.8, equally distributed across conditions, $p > .05$). Mean RTs were 501 ms for the high-frequency and 500 ms for the low-frequency items. No difference in ease of recognition was observed, $t(11) < 1$. Finally, the objective visual-complexity norms of the pictures (Szekely et al., 2004) did not differ between high-frequency and low-frequency items, $t(124) < 1$. Note that word age of acquisition – the age at which a word is first learned – tends to correlate with lexical frequency (see for discussion Bonin, Barry, Méot, & Chalard, 2004). To control for this variable, Dutch norms were obtained for 103 of our 126 picture names from Moors et al. (2013). Mean age of acquisition was similar for the words in the high- and low-frequency conditions (5.1 and 5.0 respectively, $t(98) < 1$). Although norms for 23 words were not included in the analysis, there is no a priori reason to assume that these remaining 23 words would differ from the 103 included words. Thus, given that the pictures are recognised equally fast in the two lexical-frequency conditions and they do not differ in the degree of visual or phonological complexity, nor in word age of acquisition, any differences observed across them, either in the naming latencies or in the EEG, should be attributed to the lexical-frequency effect, indicating access to long-term memory.

2.3. Design

In the experimental lists, all 126 target pictures were included, once associated with a constraining sentence and once with a nonconstraining sentence. All 252 sentences were pseudo-randomised with one *unique* list per participant using Mix (Van Casteren & Davis, 2006). The randomisation was constrained such that (1) there were at least 20 trials intervening between the two presentations of a given picture and (2) the same condition appeared at most in three consecutive trials. Moreover, 48 comprehension questions were interleaved randomly between the experimental sentences.

2.4. Procedure

Participants were tested individually in an electrically and acoustically shielded room. The stimuli

subtended 1° to 1.3° visual angle when projected on the screen placed 90 cm in front of the participants. Before the experiment, participants were instructed to keep fixation on the centre of the screen, to minimise (head) movement during the experimental blocks, to keep their lips apart when not producing a word, and to blink only at the blinking moments. These instructions were practised with 12 trials for which a fixation cross was displayed for 500 ms, followed by a picture to be named for 2 sec, followed by *** for 2 sec, indicating that participants were allowed to blink. The practice was repeated in case a participant did not conform to the instructions. Next, a familiarisation phase was conducted during which participants were shown all experimental pictures one by one on the screen following the same trial structure as the practice. After 600 ms of picture presentation, the target picture name appeared on top of the picture. Participants were instructed to read the picture name aloud and to use the respective labels in the remainder of the experiment. The experiment proper followed. A trial began with a fixation cross presented for 500 ms. The first word of the sentence followed. Each word of the sentence was presented for 300 ms, interleaved with a blank screen for 300 ms. The picture was presented for 2 sec, followed by *** for 2 sec, which was the blinking interval. Participants were instructed to read the sentences attentively and to name the pictures. Moreover, they were told to respond to the comprehension questions by saying 'yes' or 'no'. The 252 experimental trials were divided into 12 blocks with self-paced breaks in between. The whole session, including participant preparation, lasted approximately 1 hour and 15 minutes.

2.5. Data Acquisition

A microphone in the shielded room was connected to a PC, in which the Presentation Software (Neurobehavioral Systems) controlled stimulus presentation and the recording of the vocal responses. EEG was recorded from 26 scalp electrodes mounted in an elastic cap, positioned according to the international 10-20 system, using the Acticap system, amplified with BrainAmps DC amplifiers (500 Hz sampling, 0.016 – 100 Hz band-pass). Each electrode was referenced on-line to the left mastoid and re-referenced off-line to averaged mastoids. The electrooculogram was

1 recorded horizontally from the electrodes placed on the left and right temples and vertically from
2 the electrodes positioned below and above the left eye. Surface electromyogram was recorded from
3 the orbicularis oris muscle with two electrodes placed on the left upper and right lower corner of the
4 mouth. Electrode impedance was kept below 8 k Ω .
5
6

7 **2.6. Statistical Analysis of Naming Latencies**

8
9 The experimenter evaluated participants' vocal responses in real time. Responses containing a
10 disfluency, a wrong pronunciation of the word, or a wrong response word were coded as errors and
11 the corresponding trials were excluded from all subsequent analyses. Errors were not analysed due
12 to their low occurrence (3.8%). We submitted naming latencies to by-participant (F_1) and by-item
13 (F_2) analyses of variance with context (constraining and nonconstraining) and lexical frequency
14 (high and low) as independent variables. Moreover, we analysed the distribution of the naming
15 latencies by means of Vincentising (Ratcliff, 1979). For that, we rank-ordered the naming latencies
16 for each participant and context type separately and divided them into 20% quantiles. We then
17 averaged the quantiles across participants and context type.

33 **2.7. EEG Preprocessing**

34 The EEG analyses were performed using FieldTrip (Oostenveld, Fries, Maris, & Schoffelen, 2011),
35 an open-source Matlab toolbox. All trials excluded from the naming latencies analysis were also
36 excluded from the EEG analysis. Trials were cut from the raw data using two schemes, one centred
37 on the time of picture presentation (picture segments), and the other starting at the presentation of a
38 word (word segments). In the first scheme, picture segments were cut from 800 ms pre-picture
39 onset (thus, including the last written word of the sentence) to 800 ms post-picture onset. In the
40 second scheme, word segments were cut from the presentation of the first word of the sentence until
41 1.2 sec (thus, including the first two words of the sentence). The same scheme was also used for the
42 third-to-last word of the sentence.

65

before participants responded. In total, we rejected 11% of the data, equally distributed across conditions, $t(14) < 1$. Four peripheral channels were excluded (F7, F8, T7, T8) due to a high noise level. After artefact rejection, an average of 107 segments per participant remained in each context condition, and an average of 54 segments in each context-by-lexical-frequency condition.

2.8. Time-Frequency Representations of Oscillatory Power around Picture Presentation

TFRs of power were computed for the picture segments time-locked to picture presentation onset, ranging from 600 ms pre-picture to 600 ms post-picture onset, at frequencies ranging between 2 and 30 Hz, using a sliding time window of three cycles advanced in steps of 10 ms and of 1 Hz. The data in each time window was multiplied with a Hanning taper, followed by a Fourier transform. For the comparison between constraining and nonconstraining contexts, per participant, the TFRs were averaged over trials for each context type. For the comparison between the lexical frequency conditions, per participant, the TFRs were averaged over trials for each combination of context type and lexical frequency. Finally, we addressed the evolution of power changes in the course of the sentence for the context effect by estimating spectral power for the word segments in the same way as for the picture segments. No effects were observed in the gamma band (30-100 Hz) and, therefore, we do not specify those analyses here.

2.9. Event-Related Potentials around Picture Presentation

Prior to time-locked averaging, single trials were filtered with a lowpass zero-phase shift Butterworth filter with a cutoff frequency of 20 Hz. Trials with naming latencies shorter than 550 ms were excluded to avoid contamination of the ERPs with articulation artefacts.

The artefact-free epochs were further segmented to last until 500 ms after picture presentation onset. The direct current (DC) component was removed from the data by subtracting the average potential of the whole epoch. Moreover, single waveforms were baseline-corrected using the average EEG activity in the interval between 200 ms prior to the presentation of the last word of the sentence until the onset of the last word (i.e., -800 to -600 ms pre-picture onset). For the statistical analyses of the context effect, averaged ERPs were computed per participant over

1 trials for each context type. For the comparison between the lexical frequency conditions, per
 2 participant, the ERPs were averaged over trials for each combination of context type and lexical
 3 frequency.
 4 frequency.

6 **2.10. Statistical Analysis**

8 The sentential-context and lexical-frequency effects were statistically evaluated using a non-
 9 parametric cluster-based permutation test (Maris & Oostenveld, 2007). We briefly describe the
 10 method and the parameters used in the analysis but refer to the original article for a detailed
 11 description. In essence, this statistical test is time-, frequency-, and channel-uninformed. That is, the
 12 full time-frequency-channel space was blindly scanned for adjacent time points, frequencies, and
 13 channels that exhibit a similar difference across conditions. For the ERPs, the search space was
 14 formed by time points and channels only. Crucially, the false alarm rate of this non-parametric
 15 cluster-based permutation test is controlled at the alpha level (in this study, 0.05) that is used for
 16 determining statistical significance (see Maris & Oostenveld, 2007).

 25
 26
 27
 28
 29
 30

31 The statistical tests included all 22 analysed channels and time points (i.e, the full time and
 32 channel space). Channels were set to have, on average, 3.8 neighbours. For the TFRs, frequencies
 33 between 2 and 30 Hz were entered into the analysis (i.e., the full frequency space). The adjacent
 34 time-frequency-channel points (TFRs) or time-channel points (ERPs) were clustered based on a pre-
 35 determined *t*-value threshold of ± 2.14 (i.e., an alpha-level of .05 with 14 degrees of freedom). To
 36 calculate the permutation *p*-value, we used the Monte Carlo method involving 1000 random
 37 permutations. A Monte Carlo cluster *p*-value below 5% (two-tailed testing) was considered
 38 significant.

 49

50 The following tests were conducted. For the picture segments (from the last word of the
 51 sentence until 600 ms after picture onset), the context effect was evaluated by comparing the
 52 constraining and nonconstraining context types. For the word segments, the context effect was
 53 examined with one non-parametric permutation test at each word, starting with word onset and
 54 lasting for 600 ms. The lexical-frequency effect was evaluated by comparing the high- and the low-
 55

frequency conditions for each context type separately.

3. Results

3.1. Sentential Context Modulates Naming Latencies, ERPs, and Pre-Picture Alpha- and Beta-Band Power

Figure 1 (left panel) shows the mean naming latencies and the cumulative distribution of the naming latencies as a function of context, with 95% confidence intervals around the mean (calculated over the variance by participants). Naming responses were faster in the constraining than in the nonconstraining context, $F_1(1,14) = 145.3, p < .001, F_2(1,124) = 269.5, p < .001$. The cumulative RT distribution shows that the context effect is the result of a shift of the entire curve as a function of context. This means that, regardless of how fast participants named the pictures, the naming responses were always slower when the context was not constraining towards the picture name, strongly indicating that the context aided the word planning process.

Grand-average ERPs for the context and lexical-frequency conditions are shown in Figure 2, averaged over five representative channels (coloured red in the montage depicted in the left corner). For statistical evaluation, we used a cluster-based permutation test (Maris & Oostenveld, 2007), which controls the false alarm rate in the context of the very large number of (channel, time)-pairs at which the effect of interest is evaluated. This test, which was frequency, time, and channel uninformed, revealed a statistically significant difference between the constraining and nonconstraining contexts ($p = .008$) that could be attributed to a spatio-temporal cluster of adjacent channels and time-points that exhibited a more negative-going ERP amplitude in the constraining context than in the nonconstraining context. This cluster was detected between 16 ms pre-stimulus and 136 ms post-stimulus (left shaded area of Figure 2) over the channels highlighted in white in the left topographical map. Additionally, a second statistically significant difference was detected between the constraining and nonconstraining contexts ($p = .024$) that could be attributed to a spatio-temporal cluster of adjacent channels and time-points that exhibited more positive-going ERPs for constraining than nonconstraining contexts. This cluster was detected between 270 and

386 ms (middle shaded area of Figure 2) over the channels highlighted in white in the middle topographical map. Note that, contrary to common practice, here this effect is displayed as the difference for the constraining relative to the nonconstraining condition (i.e., portraying the effect as more positive-going for constraining than nonconstraining contexts rather than as more negative-going for nonconstraining than constraining contexts, like the effect of sentential constraint on the classic N400 effect in language comprehension studies). We did this to keep the ERP analysis consistent with our TFR analysis.

Using a cluster-based permutation approach that was frequency, time, and channel uninformed (Maris & Oostenveld, 2007) while controlling for the false alarm rate, a statistically significant difference was revealed between the constraining and nonconstraining contexts that could be attributed to a spectro-spatio-temporal cluster of adjacent frequencies, time-points, and channels that exhibited a similar difference between the constraining and nonconstraining conditions ($p < .001$). These results are shown in Figure 3A, which presents the relative power decreases for the constraining relative to the nonconstraining context, and in Figure 3B, where the significant cluster is indicated as highlighted activity at six different channels, whose position is shown to the right. The cluster was detected over the channels highlighted in black in the montage on the right of Figure 3A. Power decreased for the constraining relative to the nonconstraining context in the 7 to 30 Hz alpha-beta range already in the interval prior to the presentation of the picture, roughly between 400 ms pre- to 200 ms post-picture onset. The effect was most prominent in left parietal electrodes, as shown in the scalp topography to the right in Figure 3A. These findings indicate that desynchronisation in the alpha- and beta-bands with constraining relative to nonconstraining context already occurs before the picture is presented.

We addressed the progression of the power decreases for the context effect over the course of processing the sentence. The result is presented in Figure 4 for the first two and last three words of the sentences and for the picture. As can be seen in the TFR panels, at the beginning of the sentence, there are no clear modulations in power as a function of context, neither for the first word

($p = .700$), nor for the second word of the sentence ($p = .680$). As the sentence develops, context starts modulating power for the third-to-last word of the sentence ($p = .004$) and for the second-to-last word ($p = .035$). These decreases occur between 400 to 600 ms after word presentation in the 8-15 Hz alpha range. At the last word before picture presentation, power modulations were also observed ($p < .001$). Here, power decreases in the 6-30 Hz alpha-beta range started already around 100 ms after word presentation. During picture presentation, power was also modulated ($p = .003$). For this cluster, the same scalp topography and frequency range is seen as for the last word pre-picture presentation, with power decreases lasting until about 300 ms after presentation of the picture. These findings indicate that the alpha-beta power decreases between 8 and 30 Hz observed as a function of sentential constraint (shown in Figure 3) start no earlier than around the last word of the sentence preceding picture presentation.

3.2. Lexical Frequency Differentially Affects Naming Latencies and Pre-Picture Theta-Band Power as a Function of Sentential Context

Figure 1 (right panel) presents the naming latencies as a function of context and lexical frequency (white background) and the mean paired difference between high- and low-frequency picture names (grey background). Naming responses were faster for high- than for low-frequency picture names, but only in the by-subject analysis, $F_1(1,14) = 18.4$, $p < .001$, $F_2(1,124) = 1.7$, $p = .190$. Context and lexical frequency interacted, $F_1(1,14) = 5.4$, $p = .036$, $F_2(1,124) = 3.9$, $p = .050$. Thus, the effect of lexical frequency was assessed for each context separately. Simple-effect analyses confirmed that the lexical-frequency effect was only present in the nonconstraining context, $F_1(1,14) = 24.4$, $p < .001$, $F_2(1,124) = 4.3$, $p = .039$, but not in the constraining context, $F_s < 1$. Additional analyses indicated that this effect is not confounded with differences in the number of phonemes between the picture names (see Supplement).

Using a cluster-based permutation approach with no a priori definition of time windows, frequencies, or channels (Maris & Oostenveld, 2007), a statistically significant difference was revealed between the high-frequency and low-frequency conditions in the constraining context ($p =$

.013). This difference was attributed to a spectro-spatio-temporal cluster of adjacent frequencies, time-points, and channels that exhibited a similar difference between the high-frequency and low-frequency conditions. These results are shown in Figure 5A, which presents the relative power increases for the high-frequency relative to the low-frequency condition, and in Figure 5B, where the significant cluster is indicated as highlighted activity at six different channels, whose position is shown to the right. The statistically significant cluster for the lexical-frequency effect in the constraining context was detected in the 4 to 10 Hz theta range, between 500 ms pre-picture onset and 0 ms (picture onset), over the channels highlighted in black in the montage to the right of Figure 5A. The effect was most prominent in parietal electrodes, as shown in the scalp topography to the right in Figure 5A. Additional analyses indicated that this effect is not confounded with differences in the number of phonemes between the picture names (see Supplement). For the nonconstraining context, shown in Figure 5C, no modulations of power were observed as a function of lexical frequency.

The grand-average ERPs for the lexical-frequency conditions are shown in Figure 2, averaged over five representative channels (coloured red in the montage depicted in the left corner of Figure 2). No significant clusters were observed in the ERPs for the lexical-frequency effect.

4. Discussion

In the present study, we investigated the electrophysiological signatures of lexical frequency and sentential constraint in spoken word production. Participants read sentences that were either contextually constraining or nonconstraining towards one target word. The last word of the sentence was presented as a picture that had to be named, and the picture name could be of high or low frequency.

4.1. The Effect of Sentential Constraint

Our main findings for the context effect can be summarised as follows. In the naming responses, shorter latencies were observed for pictures following a constraining relative to a nonconstraining context, in line with previous literature (Griffin & Bock, 1998), suggesting that the

manipulation of context was successful in modulating the ease of word production. In the ERPs, a negativity was observed for constraining relative to nonconstraining context around picture presentation. Post-picture onset, the ERPs were more negative-going for nonconstraining relative to constraining context, in line with the classical N400 effect (Kutas & Hillyard, 1980) in the language comprehension literature (see Kutas & Federmeier, 2011).

In the TFRs, we observed decreases in alpha and beta power starting already before picture presentation for constraining relative to nonconstraining sentences. Specifically, at the third- and second-to-last words of the sentence, power decreased in the 8-15 Hz alpha range between 400 and 600 ms after word presentation, whereas at the last word before picture presentation and at picture presentation, the power decreases comprised a broader alpha-beta frequency range (6-30 Hz). Since the last word of the sentences was always either a determiner or an adjective matched for lexical frequency and word length, we can be confident that the pre-picture effects (observed between 600 ms pre-picture onset to picture presentation) are not driven by differences in the word presented, but rather by differences in the sentential constraint as a whole.

4.1.1. Alpha- and beta-power decreases

It is well known that language users can anticipate linguistic material, even to the level of pre-activating (retrieving) specific words (for a review, see Kutas, DeLong, & Smith, 2011). Evidence that access can begin already pre-picture presentation in our study is provided by the shorter naming latencies with constraining context and by the theta-band power modulations in the constraining context, which are discussed in section 4.2.1 below. Accordingly, our pre-picture alpha-band activity may be related to (lexical) retrieval processes (e.g., Khader & Rösler, 2011; Mellem et al., 2012) and to semantic memory (Röhm et al., 2001; Klimesch, 1999; Klimesch et al., 1997). However, this account is unlikely to be complete. Firstly, the lexical-frequency effect (a core index of memory processes) was associated with theta rather than alpha activity. Moreover, it has been shown that, when lexical–semantic prediction leads to the pre-activation of both visual word-forms and lexical representations, modulations in the theta band are observed (Dikker & Pylkkänen,

2012). Furthermore, the alpha-band activity was more prominent in a later time window (400 ms pre- to 200 ms post-picture presentation) than the theta-band activity (500 ms pre-picture to picture presentation). Of course, we cannot rule out the possibility that the alpha-band effects may also be reflecting lexical processing (e.g., Mellem et al., 2012), with different aspects of lexical access reflected in different frequency bands (see for similar proposals, e.g., Khader & Rösler, 2011; Klimesch, Freunberger, Sauseng, & Gruber, 2008; Klimesch, Freunberger, & Sauseng, 2010; Mellem et al., 2012). Future research should be able to better clarify these issues.

Importantly, given that participants are in a setting in which they have to name pictures and, in many cases, they are able to predict the lexical item (the picture name), assembling the motor programme for articulation can also be initiated. Motor preparation and execution is known to be reflected in power decreases in the alpha and beta bands (e.g., Alegre et al., 2004; McFarland et al., 2000; Neuper et al., 2006; see for a review Cheyne, 2012), an account that would be in line with the present findings of alpha- and beta-power decreases for constraining relative to nonconstraining contexts.

Alternatively, it could be argued that our alpha-power decreases relate to attention and sensory expectation of the upcoming visual stimulus, i.e., the picture (e.g., Klimesch, 1999; Klimesch et al. 1997; Klimesch, Doppelmayr, Russegger, Pachinger, & Schwaiger, 1998; Van Ede et al., 2011, 2012). However, signal modulations due to expectation of a visual stimulus are commonly observed in the alpha band over occipital-parietal channels (e.g., Romei et al., 2010; Thut, Nietzel, Brandt, & Pascual-Leone, 2006; Worden, Foxe, Wang, & Simpson, 2000). This is consistent with only part of our observations: Only the modulations for the third- and second-to-last words are in the alpha range (8-15 Hz) and have a mainly occipital-parietal scalp distribution (see Figure 4). The power modulations around the last word (400 ms pre-picture onset), in turn, have a more fronto-central distribution and a wider spectrum (6-30 Hz), suggesting a process different from mere visual expectation. Thus, for now, we argue that our present alpha- and beta-band activity may be better explained in terms of motor preparation for speaking, presumably including

assembling the motor programme of the word to be produced.

4.2. The Effect of Lexical Frequency

An important question addressed in the present study concerns the time at which contextual information can affect the access to lexical memory. The interaction between the lexical-frequency and sentential-context effects sheds light onto this issue. Naming latencies were shorter for pictures with high-frequency relative to low-frequency names only when the sentence context was nonconstraining, replicating Griffin and Bock (1998). Presumably, in a nonconstraining context, lexical access starts with the presentation of the picture, allowing for variables that affect the speed of access (e.g., lexical frequency; see Jescheniak & Levelt, 1994; Kittredge et al., 2008), to be reflected in the naming latencies. In line with this hypothesis, with a nonconstraining context, no differences in the EEG as a function of lexical frequency were observed pre-picture onset.

With a constraining context, in turn, memory access can already be guided before the picture is presented, which would explain why an effect of lexical frequency is absent in the naming latencies (but see Griffin & Bock, 1998). Naturally, if access of the picture name is initiated before picture presentation, an effect of lexical frequency should occur in a time window preceding the picture. This is indeed what we found in the oscillatory brain activity. In the TFRs of the constraining context, theta power increased for the high-frequency relative to the low-frequency picture names before picture presentation (-500 to 0 ms). This finding suggests that contextual constraints already guide the access of lexical representations for production before the presentation of the picture, that is, in the absence of the stimulus representing the target concept, contrary to what Griffin and Bock (1998) assumed.

For nonconstraining sentences, using a time- and channel-uninformed analysis, we did not observe modulations of the ERPs as a function of lexical frequency¹, a finding that is not in agreement with previous reports of the lexical-frequency effect modulating ERP components

¹ When using a time-informed test, constrained to 300-500 ms (e.g., Strijkers et al. 2011), a statistically significant cluster was detected for the lexical-frequency effect ($p = .029$), with a more negative-going ERP amplitude in the low-frequency than in the high-frequency condition.

(Laganaro et al., 2009; Strijkers et al., 2010). However, the paradigms used in these previous studies - standard and delayed picture naming - were very different from our paradigm, so it remains difficult to directly compare these findings. Moreover, our study had fewer trials per lexical-frequency condition relative to the other studies, which could also be a factor partly explaining the differences.

4.2.1. Theta-band effects

The observed theta-power modulations can be best interpreted as reflecting the access of lexical representations from long-term memory. This finding is in line with observations that, in the human neocortex, a clear relation exists between memory processes and theta-power changes (for reviews, see Düzel et al., 2010; Klimesch et al., 2010; Nyhus & Curran, 2010). This result also agrees with the proposal from the language comprehension literature that a relation exists between the theta rhythm and the retrieval of lexical-semantic information (Bastiaansen et al. 2005, 2008).

The theta power increase for high-frequency relative to low-frequency picture names merits further investigation. Increases in theta-band power in memory tasks have been previously associated with higher memory-trace strength relative to lower strength (e.g., Klimesch et al., 2006) and successful memory retrieval (i.e., correctly recognised old items versus correctly identified new items, e.g., Klimesch, Doppelmayr, Schwaiger, Winkler, & Gruber, 2000; Osipova et al., 2006), among others. Our findings can be explained by memory-trace strength (high-frequency words have a stronger memory trace) and retrieval success (high-frequency words may be easier to retrieve). Future investigations of memory retrieval in language production should be able to address these questions, which at the moment remain speculative.

4.3. Differences between ERPs and oscillations

In our study, the ERP effects were quite distinct from the oscillatory effects in both their time course and scalp topography (see also Davidson & Indefrey, 2007; Laaksonen et al., 2012). These results highlight the possibility that these two types of measures are qualitatively different (see e.g., Davidson & Indefrey, 2007; Laaksonen et al., 2012). In fact, the cue for access of the

1 picture name in the two sentential contexts is quite different, i.e., either brought about by the
2 presentation of a visual cue (the picture) representing the concept to be expressed (nonconstraining
3 context) or driven by a slow build-up of converging conceptual information provided by the
4 sentential context (constraining context). In this latter case, the converging conceptual information
5 is not found consistently at a single point within the sentence, so over trials, lexical information is
6 being retrieved at different points in time. This means that the access process will not be locked to a
7 specific time point, and therefore, it is not reflected in the ERPs, which are by definition a measure
8 of activity that is consistently locked to a specific time point. When the cue to retrieve lexical
9 information is the picture, the access process is more likely to be consistently time locked over
10 trials, resulting in an ERP response (e.g., Laganaro et al., 2009; Strijkers et al., 2010). This
11 explanation is in line with the distinction between phase-locked (ERPs) and non-phase locked
12 (oscillations) responses (Bastiaansen, Mazaheri, & Jensen, 2012) and it could be more directly
13 addressed by future language studies of memory access and retrieval comparing ERPs and
14 oscillations.

33 **4.4. Conclusions**

34 Using a task in which participants named pictures after reading sentences, we manipulated
35 sentential constraint and lexical frequency, and assessed how these manipulations modulated ERPs
36 and oscillatory brain responses. Our findings not only replicated previous behavioural findings on
37 single word production, but also extended these findings to the domain of oscillations in relation to
38 spoken word production in sentential context. We observed theta power increases before picture
39 presentation for high- relative to low-frequency picture names only in constraining contexts,
40 suggesting an electrophysiological marker of lexical access based solely on the contextual cues. Our
41 electrophysiological data suggest that the interaction between lexical frequency and sentential
42 constraint occur already before picture onset, unlike what Griffin and Bock (1998) assumed.
43 Furthermore, alpha- and beta-power decreases were observed around picture presentation for
44 constraining relative to nonconstraining contexts, suggesting preparation of the speech motor-

programme. Altogether, these results characterise the oscillatory brain responses induced by two
fundamental factors affecting spoken word production, and point to possible avenues for studying
the neurophysiological basis of spoken language production.

Table 1. Mean cloze probabilities for the 126 pictures (target) in the constraining and nonconstraining contexts, calculated as the first-response probability (1st) and as the overall probability (O.), and example sentence frames.

Context	1 st	O.	Example sentence frame	Target
Con.	76	90	Tijdens de kampeervakantie zat hij nauwelijks in de	tent
			<i>During the camping vacation, he was rarely in the</i>	<i>tent</i>
			Om cellen te kunnen zien, gebruikt men een	microscop
			<i>In order to see cells, one uses a</i>	<i>microscope</i>
Noncon.	1	4	Gedurende de dag was hij nauwelijks in de	tent
			<i>During the day, he was rarely in the</i>	<i>tent</i>
			Om dit te kunnen zien, gebruikt men een	microscop
			<i>In order to see this, one uses a</i>	<i>microscope</i>

Note: O. = Overall; Con. = Constraining; Noncon. = Nonconstraining.

Figure 1. **Behavioural data. Left panel.** Vincentised cumulative response-time distribution curves for the constraining (dashed line) and nonconstraining (continuous line) contexts. The mean naming times for each condition are given in the lower part of the figure. **Right panel. White background.** Mean naming times and 95% confidence intervals around the mean as a function of sentential context and lexical frequency. *Grey background.* Mean paired difference (low – high frequency) and its 95% confidence interval, whose zero is centred at the constraining context mean, as a function of context. N = Nonconstraining; C = Constraining.

Figure 2. **Event-related potentials.** Event-related potentials (ERPs) to the last word of the sentence and to the picture as a function of sentential context and lexical frequency. The presented ERPs are the average over the five representative channels highlighted in red in the montage depicted in the left corner. The scalp distributions of the sentential-context effect (constraining vs. nonconstraining) are shown averaged over the significant time windows (grey shaded areas) of -16 to 136 ms (left) and 270 to 386 ms (right). The channels participating in the significant clusters are highlighted in white in the topographical maps. The boxes below the figure exemplify the events in the trial. C = Constraining; N = Nonconstraining.

Figure 3. **Time–frequency representation of the sentential-constraint effect. A.** Time-frequency representation of the sentential-constraint effect, represented as relative power changes (constraining vs. nonconstraining), averaged over the significant channels (highlighted in the scalp topography to the right). The scalp distribution (right) displays the sentential-constraint effect, averaged over the significant time window of -400 to 200 ms in the 6 to 30 Hz range. The boxes below the figure exemplify the events in the trial. **B.** Significant spectro-temporal clusters for the sentential-constraint effect at the six electrodes indicated on the right.

Figure 4. **Time course of the sentential-constraint effect.** Time-frequency representations (TFRs) and topographical maps of the sentential-constraint effect, represented as relative power changes (constraining vs. nonconstraining), over the course of the sentence, with the trial events shown below. The TFRs show the activity for the channel CP1, marked in black (big dot) in the maps. The significant clusters are indicated as highlighted activity in the TFRs and highlighted channels (in black) in the maps. The first and second columns display the activity at the first and second words of the sentence. The third to fifth columns display the activity for the last three words of the sentence before picture presentation. The last column displays the activity at picture presentation. Rel. = Relative.

Figure 5. **Time–frequency representation of the lexical-frequency effect.** **A.** Time-frequency representation (TFRs) of the lexical-frequency effect for the constraining context, represented as relative power changes (high vs. low frequency), averaged over the significant channels (highlighted in the scalp topography to the right). The scalp distribution (right) displays the lexical-frequency effect averaged over the significant time window of -500 to 0 ms in the 4-10 Hz range. The boxes below exemplify the events in the trial. **B.** Significant spectro-temporal clusters for the lexical-context effect at the six electrodes indicated on the right. **C.** TFRs of the lexical-frequency effect for the nonconstraining context, represented as relative power changes (high vs. low frequency), averaged over the channels highlighted in the topographical map in A. The boxes below exemplify the events in the trial.
