Abstract. The strong coupling constant, $\alpha_s$, has been determined in hadronic decays of the $Z^0$ resonance, using measurements of seven observables relating to global event shapes, energy correlations and jet rates. The data have been compared with resummed QCD calculations, which are combined with the $\mathcal{O}(\alpha_s^2)$ theory. The seven measurements agree to about 10%, and the final result, based on a weighted average, is:

$$\alpha_s(M_{Z^0}) = 0.120 \pm 0.006,$$

where the error includes both experimental and theoretical uncertainties. This value corresponds to renormalization scale $\mu = M_{Z^0}$ and the error includes the uncertainty in this choice of scale. The present measurement complements previous determinations using the $\mathcal{O}(\alpha_s^2)$ QCD matrix elements alone, and yields a compatible result, with comparable errors.

1 Introduction

The measurement of the strong coupling constant, $\alpha_s$, is a basic test of the strong interaction sector of the Standard Model, Quantum Chromodynamics (QCD) [1]. The predictions of QCD are governed by just one fundamental coupling strength. It is therefore important to measure $\alpha_s$ in as many different ways as possible, since consistency between the measurements would serve as a test of the QCD matrix elements alone, and yields a compatible result, with comparable errors.

$$\alpha_s(M_{Z^0}) = 0.120 \pm 0.006,$$

theory. Knowledge of the value of $\alpha_s$ and an understanding of QCD are also important ingredients of many electroweak tests at LEP. Furthermore, an accurate determination of $\alpha_s$ is an important constraint in speculations about unification of the electroweak and strong interactions at very high energies (see e.g. [2] and references therein).

The conventional method by which $\alpha_s$ has been determined involves comparing experimental data with QCD calculations based on an order-by-order expansion in powers of $\alpha_s$. In the case of the process $e^+ e^- \rightarrow$ hadrons the QCD matrix elements are fully known to $\mathcal{O}(\alpha_s^2)$, corresponding to final states containing no more than four partons. Predictions for the distributions of many observables to $\mathcal{O}(\alpha_s^2)$ based on these matrix elements have been given in [4]. In a recent publication [5] the OPAL collaboration determined $\alpha_s(M_{Z^0})$ from 13 different observables in $\mathcal{O}(\alpha_s^2)$, and after making reasonable estimates of experimental and theoretical uncertainties found that the values were compatible. The final uncertainty on the value of $\alpha_s(M_{Z^0})$ was about 5%, the accuracy being mainly limited by theoretical uncertainties, particularly relating to higher order effects and hadronization. Other measurements of $\alpha_s$ at LEP to $\mathcal{O}(\alpha_s^2)$ have been presented in [6–17]. Measurements of $\alpha_s$ at LEP to $\mathcal{O}(\alpha_s^2)$ using the total hadronic cross-section and the hadronic decays of the $\tau$-lepton are summarised in [18, 19].

This standard procedure, based on the $\mathcal{O}(\alpha_s^2)$ matrix elements, is unsuccessful in describing the back-to-back two-jet region of phase space. In this region multiple emissions of soft gluons may be expected to be important. An alternative approach may be taken to the QCD calculations of hadronic final states in $e^+ e^-$ annihilations, based on the resummation of leading logarithms which arise from soft and collinear singularities in gluon emission. The consequence is that the effective expansion pa-
rameter is not simply $\alpha_s$, but $\alpha_s L^2$ (to leading order in $L$), where $L = \ln(1/y)$ and $y$ is some generic observable which tends to zero in the two-jet region. At small $y$ the value of $\alpha_s L^2$ is not small, and therefore these terms must be summed to all orders in $\alpha_s$ in order to provide a satisfactory calculation. For certain observables it has proved possible to sum both the leading and next-to-leading logarithms, which we refer to as the "Next-to-leading log approximation" or NLLA. In the present paper we consider seven observables describing the final state in $e^+e^-\rightarrow$ hadrons for which NLLA calculations are available: thrust [20,21], heavy jet mass [22,21], two measures of jet broadening [23], energy-energy correlations [24,25], two-jet rates [26] and average jet multiplicities [27] (though in the latter two cases the next-to-leading terms have been only partially resummed). First results using the thrust and heavy jet mass observables were given in a previous OPAL paper [5], and other analyses of LEP data in the NLLA framework have been presented in [28-30]. A recent compilation of measurements of $\alpha_s$ based on both the $\mathcal{O}(\alpha_s^2)$ and the NLLA approaches is given in [18].

The NLLA calculations are expected to be most reliable in predicting the parton distributions in the two-jet region. Unfortunately this region is subject to particularly large hadronization effects, which introduce significant uncertainties when confronting the theory with data. We therefore do not determine $\alpha_s$ simply from the NLLA calculations. Instead the NLLA calculation is obtained, which will give an indication of the reliability of observables than has hitherto been possible we can separate, and might therefore allow a reduction in the systematic error in $\alpha_s$. We explore this possibility in the present paper. By applying the method to a wider range of observables than has hitherto been possible we can look for consistency between the different values of $\alpha_s$ obtained, which will give an indication of the reliability of this approach to the QCD calculations. By comparing the results with those from the conventional $\mathcal{O}(\alpha_s^2)$ technique we hope to gain further insight into higher order effects.

The present paper is organized as follows: a brief account of the OPAL detector and data selection procedures is given in Sect. 2, and the observables used and the methods adopted for correcting the data are described in Sect. 3. The application of the NLLA and $\mathcal{O}(\alpha_s^2)$ QCD calculations to the determination of $\alpha_s$ is presented in Sect. 4. Finally Sect. 5 contains a summary and some discussion of the results.

2 The OPAL detector and data selection

A detailed description of the OPAL detector has been presented in [31], and therefore only a short account of some of its features relevant to the present analysis will be given here.

The momenta of charged particles are measured in the central tracking detectors. For this analysis we use three drift chamber systems. A precision vertex chamber, of radius 24 cm and length 100 cm provides space points with resolution about 50 $\mu$m in the $r-\phi$ plane*. This is surrounded by a large jet chamber, of radius 185 cm and length about 400 cm, which provides up to 159 digitizations with an $r-\phi$ resolution of around 130 $\mu$m. Outside this lies a system of $z$-chambers, to improve the resolution in $\theta$. The central detector lies within an axial magnetic field of 0.435 T.

The electromagnetic calorimeter consists of a barrel of 9440 lead glass blocks oriented so that they nearly point to the interaction region, and two endcaps of 1132 lead glass blocks each, aligned along the $z$-axis. Each block subtends approximately 40 × 40 mrad² at the origin, and the overall coverage is about 98% of 4$\pi$. In addition to measuring the energies of electrons and photons, the electromagnetic calorimeter records a significant fraction of the energy of charged and neutral hadrons.

The OPAL trigger [32] has a high degree of redundancy, so that the efficiency for accepting multi-hadronic events is extremely high, greater than 99.9%. The online filter and offline selection procedures are described in [33,34], and are again highly efficient. For the present analysis further cuts were applied to remove residual background and provide a sample of well contained events. The collision energy was required to lie within 0.5 GeV of the $Z^0$ mass, and those parts of the detector essential for the present analysis (central detector and electromagnetic calorimeter) were required to be fully operational. Charged tracks accepted for this analysis were required to satisfy the following criteria: transverse momentum with respect to the collision axis greater than 0.15 GeV/c, at least 40 reconstructed points in the jet chamber, extrapolation to the collision point within 2 cm in $r-\phi$ and 25 cm in $z$ and measured momentum less than 60 GeV/c. The number of such tracks was required to be at least five to reduce $\tau^+\tau^-$ background. Clusters of electromagnetic energy were used if their observed energy was greater than 0.25 GeV, and known noisy channels in the detector were removed. The thrust axis (Sect. 3.1) was determined using all tracks and clusters satisfying these criteria, and required to fulfill the condition $|\cos \theta| < 0.9$ in order that the event be well contained. Using these selection criteria, Monte Carlo studies indicate that, within the chosen range of $\cos \theta$, $99.86 \pm 0.07%$ of hadronic $Z^0$ decays are accepted, with a contamination of about 0.14% from $\tau^+\tau^-$ events, and around 0.07% from two-photon interactions. Using the OPAL data collected in 1990 and 1991 a data sample of 336 247 events remained for analysis after these cuts.

* The OPAL coordinate system is defined so that $z$ is the coordinate parallel to the $e^-$ beam, $r$ is the coordinate normal to this axis, $\theta$ is the polar angle with respect to $z$ and $\phi$ is the azimuthal angle about the $z$-axis.
3 Experimental procedure

3.1 The observables used for analysis

Our determination of $\alpha_s$ is based on measurements of the following variables, for all of which resummed QCD calculations are available:

- **Thrust**: The thrust $T$ is defined [35] by
  \[ T = \max \left( \frac{\sum_i |p_i \cdot \hat{n}|}{\sum_i |p_i|} \right) \]
  where $i$ runs over all the final state particles, and the axis $\hat{n}$ is chosen to maximize the value of the expression in parentheses; this axis $\hat{n}_T$ is referred to as the thrust axis. In the present analysis we use the observable $(1 - T)$, which tends to zero in the two-jet region.

- **Heavy jet mass**: This variable has been proposed in [36]. We divide the particles in an event into two groups by the plane orthogonal to the thrust axis, $\hat{n}_T$, and compute the invariant mass of each group. We define the heavier mass to be $M_H$. For the determination of $\alpha_s$ we use the scaled variable $M_H/\sqrt{s}$, where $s$ is the square of the centre-of-mass energy. In our previous publication [5] we also considered an alternative way of separating the particles into two groups. It transpired that the results from the two approaches, including all their systematic errors, were virtually identical, so in the current study we use only the simpler method based on the thrust axis. To first order in $\alpha_s$ the heavy jet mass and thrust are related by
  \[ (1 - T) = M_H/s. \]
  These observables have been suggested in [23]. Again the event is divided into two hemispheres, $S_\pm$, by the plane orthogonal to the thrust axis, $\hat{n}_T$. In each hemisphere, the quantity:

  \[ B_\pm = \frac{1}{2} \sum_i |p_i \times \hat{n}_T| \]

  is computed, where the sum in the denominator runs over all particles, whilst that in the numerator runs over one hemisphere. The observables used for the study of $\alpha_s$ are

  \[ B_T = B_+ + B_- \quad \text{and} \quad B_W = \max(B_+, B_-), \]

  referred to as the “total jet broadening” and “wide jet broadening” respectively. To leading order in $\alpha_s$, $B_T = B_W = \frac{1}{2} O$ (where $O$ is the oblateness [37]). Both $B_T$ and $B_W$ tend to zero in the two-jet region. These variables are sensitive to the transverse structure of jets, and may therefore be complementary to $(1 - T)$ and $M_H/\sqrt{s}$, which are more dependent on the longitudinal momenta.

- **Energy-energy correlation**: The energy-energy correlation function $\Sigma_{EEC}$ [38] is defined in terms of the angle $\chi_{ij}$ between two particles $i$ and $j$ in a multihadronic event:
  \[ \Sigma_{EEC}(\chi) = \frac{1}{\Delta x \cdot N} \sum_{x} \frac{1}{\Delta x} \sum_{ij} \frac{E_i E_j}{E_{vis}^2} \cdot \delta(\chi' - \chi_{ij}) d\chi', \]
  where $E_i$ and $E_j$ are the energies of particles $i$ and $j$, $E_{vis}$ is the sum over the energies of all particles in the event, $\Delta x$ is the angular bin width and $N$ is the total number of events. The normalization ensures that the integral of $\Sigma_{EEC}(\chi)$ from $\chi = 0^\circ$ to $180^\circ$ is unity.

- **Jet rates**: For the present analysis we define jets through the “Durham” scheme [26, 39, 40]. A jet resolution variable $y_{ij}$ is defined for each pair of particles $i$ and $j$ by:
  \[ y_{ij} = 2 \min\left(\frac{E_i^2 + E_j^2}{E_{vis}^2}, \frac{1}{2} \right) \left(1 - \cos \theta_{ij}\right) \]
  where $E_i$ and $E_j$ are the energies of the two particles or jets $i$ and $j$, $\theta_{ij}$ is the angle between them and $E_{vis}$ is again the sum over the energies of all particles in the event. If the smallest value of $y_{ij}$ is smaller than some cutoff $y_{cut}$, then particles $i$ and $j$ are replaced by the sum of their four-momenta. The process is repeated until all remaining pairs satisfy $y_{ij} > y_{cut}$, and the groups of particles at this stage are called “jets”. Resummed QCD calculations are available for two observables related to these jet rates; the two-jet rate:
  \[ R_2 = \frac{\sigma_{2-jet}}{\sigma_{tot}} \]
  and the average number of jets:
  \[ N = \frac{1}{\sigma_{tot}} \sum_{n=2}^{\infty} n \sigma_{n-jet} \]
  as a function of $y_{cut}$ in both cases. When performing fits to the data we have used the differential jet rate $D_2(y_{cut}) = dR_2(y_{cut})/dy_{cut}$ instead of $R_2$.

3.2 Correction of data

The observables described above were calculated from the data using both charged tracks and clusters of electromagnetic energy. A Monte Carlo simulation of the OPAL detector [41] was then used in order to correct for experimental resolution and acceptance. In this correction the effects of initial state photon radiation were also removed, although these effects are small since only data at the $Z^0$ peak energy were used. The data were further corrected for the effects of hadronization using QCD parton shower Monte Carlo models. The procedure closely followed [42]. The simplest technique employed bin-by-bin correction factors. Two Monte Carlo samples were used: a sample (I) with no initial state photon radiation and no detector simulation, and a sample (II) using the same Monte Carlo but including detector simulation and initial-state radiation. The QCD parton shower model JETSET [43], version 7.3, with parameters tuned to OPAL data on global event shapes [42], was used to
Table 1. Distributions of the variables defined in the text. The data are corrected for the finite acceptance and resolution of the detector and systematic uncertainties, added in quadrature.

As discussed in [42], this simple bin-by-bin correction procedure is reliable only if the bin width selected for the data is greater than or comparable with the experimental resolution, so that migration between bins is small. In the case of the event shape variables \((1 - T), M_H, B_T, B_w\), the effective resolution resulting from hadronization and detector effects is quite large, which requires that a large bin width be employed in the bin-by-bin procedure. Therefore an alternative approach was adopted for these observables in order to be able to use a somewhat finer binning. Using the events in sample (II) which pass the selection criteria at the detector level, one can compute the matrix \(P\), in which the element \(P_{ij}\) gives the probability that an event in bin \(i\) at the hadron (or parton) level is found to lie in bin \(j\) when the detected tracks and clusters are used. Then, if \(C_i\) is the number of events in bin \(i\) at the hadron (or parton) level, we may infer the probability \(Q_{ij}\) that an event found in bin \(j\) at the detector level originated from bin \(i\) at the hadron (or parton) level:

\[
Q_{ij} = \frac{P_{ij} C_i}{\sum_k P_{jk} C_k}.
\]
The data may then be corrected to the hadron (or parton) level by:

$$C'_i = \sum_j Q_{ij} D_j,$$  \hspace{1cm} (7)

where $D_j$ is the number of observed events in bin $j$ in the data. It is clear from (6) that the matrix $Q$ depends on the true distribution $C$, initially taken from the Monte Carlo. If the corrected data $C'_i$ differ significantly from the assumed distribution $C$, then $C'$ may be substituted for $C$ in (6) and the correction procedure iterated. It was found that the value of $\alpha_s$ was extremely stable under such an iterative procedure, as expected since the Monte Carlo was already tuned to fit the data well. Finally a bin-by-bin correction was applied to account for the effects of initial state radiation and losses of events in the selection procedure - this correction turned out to be very small. We found that the data corrected using this matrix method yielded values of $\alpha_s$ which were entirely compatible with those from the bin-by-bin method. Therefore we show the matrix corrected results for $(1 - T)$, $M_H, B_T$ and $B_W$ in this paper.
In Table 1 we present data for the observables used in the present analyses, corrected for detector effects (i.e. at the hadron level). The errors include a statistical part, arising from finite statistics in both data and Monte Carlo, and a (dominant) contribution from experimental systematic effects, estimated as described in Sect. 4.3. The errors are in general correlated between bins; these effects were estimated by dividing the data and Monte Carlo samples into a number of independent subsets and computing the covariance matrix. The errors quoted in Table 1 are based on the diagonal terms of the covariance matrix, but the full matrix was available when fitting the data. In Fig. 1 we show the hadron level data for the observables which we have not presented in previous publications [5, 8], namely $B_r$, $B_w$ and $\mathcal{N}$, compared with the predictions of the parton shower models JETSET version 7.3 [43] and HERWIG version 5.5 [44], with parameters tuned to OPAL data as described in [42, 45].

4 Determination of $\alpha_s$

4.1 Combination of resummed and fixed order QCD calculations

For the present analysis, the NLLA and $\mathcal{O}(\alpha_s^2)$ calculations have to be combined before they are fitted to data. There are a number of different schemes by which this may be done, which we describe here, following the discussion in [28, 46, 21]. We consider four schemes, which we refer to as 'ln(R)-matching', 'R-matching', 'modified R-matching' and 'modified ln(R)-matching', though not all schemes are applicable to all seven observables. The various matching schemes all embody the full $\mathcal{O}(\alpha_s^2)$ result, together with the resummation of leading and next-to-leading logarithms, but they differ in higher orders. The technical details of these schemes are given in the remainder of this section.

For all the variables we are considering for which resummation is possible, with the exception of the average jet multiplicity $\mathcal{N}$, the cumulative cross-section may be written in the general form:

$$ R(y) = \int_0^y \frac{1}{\sigma} \frac{d\sigma}{dy} dy = C(\alpha_s) \exp G(\alpha_s, L) + D(\alpha_s, y), $$

where $y$ is $(1 - T)$, $M_H^2/s$, $B_r$ or $B_w$ in the case of the event shapes, $\cos^2 \left( \frac{\chi}{2} \right)$ in the case of $\Sigma_{EEC}$, and $y_{	ext{cut}}$ for the jet rates, and $L = \ln (1/y)$. $D(\alpha_s, y)$ is a remainder function which should vanish as $y \to 0$. The general structure of the cross-section in powers of $\alpha_s$ and of large logarithms is indicated in Table 2. The functions $C$ and $G$ may be written:

$$ C(\alpha_s) = 1 + \sum_{n=1}^{\infty} C_n \alpha_s^n $$

and

$$ G(\alpha_s, L) = \sum_{n=1}^{\infty} \sum_{m=1}^{n+1} G_{nm} \alpha_s^n L^m \equiv Lg_1(\alpha_s, L) + g_2(\alpha_s, L) + \alpha_s g_3(\alpha_s, L) + \alpha_s^2 g_4(\alpha_s, L) + \ldots, $$. 

where for brevity we write $\bar{\alpha}_s$ for $(\alpha_s/2\pi)$. The functions $Lg_1(\alpha_s, L)$ and $g_2(\alpha_s, L)$ represent the sums of the leading and next-to-leading logarithms respectively, to all orders in $\alpha_s$ (see Table 2). The NLLA calculations give an approximate expression for $R(y)$ in the form:

$$ R_{\text{NLLA}}(y) = (1 + C_1 \bar{\alpha}_s + C_2 \bar{\alpha}_s^2) \exp \left[ Lg_1(\alpha_s, L) + g_2(\alpha_s, L) \right]. $$

The functions $g_1$ and $g_2$ are given by the NLLA calculations; the coefficient $C_1$ is known exactly from the $\mathcal{O}(\alpha_s)$ matrix elements and $C_2$ is known (in the case of $(1 - T)$, $M_H$, $B_r$ and $B_w$) from numerical integration of the $\mathcal{O}(\alpha_s^2)$ matrix elements; their values are summarized in Table 3. The full $\mathcal{O}(\alpha_s^2)$ calculation yields an approximate expression for $R(y)$ of the form:

$$ R_{\text{\mathcal{O}(\alpha_s^2)}}(y) = 1 + \mathcal{A}(y) \bar{\alpha}_s + \mathcal{B}(y) \bar{\alpha}_s^2, $$

where the coefficients $\mathcal{A}(y)$ and $\mathcal{B}(y)$ are equivalent to the $A$ and $B$ coefficients tabulated in [4], but integrated to correspond to the cumulative distribution $R(y)$. In the case of $\Sigma_{EEC}$, $B_r$ and $B_w$ we have run the program EVENT, which was used by the authors of [4], to derive values of the coefficients.

| Table 2. Decomposition of the cumulative cross-section, $R(y)$, in powers of $\bar{\alpha}_s=(\alpha_s/2\pi)$ and $L=\ln(1/y)$. The NLLA calculations provide the terms in the first two columns, while the $\mathcal{O}(\alpha_s^2)$ calculations yield the sums of the terms in the first two rows. The matching procedures involve combining these without double-counting the terms in common |
|-----------------|-----------------|-----------------|-----------------|
| Leading logs    | Next-to-leading logs | Subleading logs | Non-logarithmic terms |
| $\ln R(y)$ =    |                  |                  |                   |

The simplest matching scheme involves taking the logarithm of (12) and expanding as a power series, yielding:

\[
\ln R(\mathcal{O}(\alpha_s^2))(y) = \mathcal{A}(y) \tilde{x}_s + \left[ \mathcal{B}(y) - \frac{1}{2} \mathcal{A}(y)^2 \right] \tilde{x}_s^2 + \mathcal{O}(\alpha_s^3),
\tag{13}
\]

and similarly rewriting (11) as:

\[
\ln R_{\text{NLLA}}(y) = L g_1(\alpha_s L) + g_2(\alpha_s L) + C \tilde{x}_s + \left[ C_2 - \frac{1}{2} C_1^2 \right] \tilde{x}_s^2 + \mathcal{O}(\alpha_s^3),
\tag{14}
\]

Removing the terms to \( \mathcal{O}(\alpha_s^3) \) in the NLLA expression (14), replacing them by the \( \mathcal{O}(\alpha_s^2) \) terms from (13) and neglecting non-logarithmic terms of higher order yields (c.f. Table 2):

\[
\ln R(y) = L g_1(\alpha_s L) + g_2(\alpha_s L) - (G_{11} L + G_{12} L^2) \tilde{x}_s - (G_{22} L^2 + G_{23} L^3) \tilde{x}_s^2 + \mathcal{A}(y) \tilde{x}_s + \left[ \mathcal{B}(y) - \frac{1}{2} \mathcal{A}(y)^2 \right] \tilde{x}_s^2.
\tag{15}
\]

This procedure will be referred to as 'ln (R)-matching'. Alternatively the analogous procedure may be carried out for the functions \( R(y) \) instead of \( \ln (R(y)) \), yielding:

\[
R(y) = \left[ 1 + C_1 \tilde{x}_s + C_2 \tilde{x}_s^2 \right] \exp \left\{ L g_1(\alpha_s L) + g_2(\alpha_s L) \right\} - (C_1 + G_{11} L + G_{12} L^2) \tilde{x}_s - (C_2 + G_{22} L^2 + G_{23} L^3 + (G_{11} L + G_{12} L^2)) \tilde{x}_s^2 + \mathcal{A}(y) \tilde{x}_s + \left[ \mathcal{B}(y) - \frac{1}{2} \mathcal{A}(y)^2 \right] \tilde{x}_s^2.
\tag{16}
\]

This procedure will be referred to as 'R-matching'. It would be expected that R-matching would be less reliable than the ln(R)-scheme, because the subleading term \( G_{21} \tilde{x}_s^2 L \), which does not vanish as \( y \to 0 \), is not exponentiated in (16), whereas it is exponentiated in (15) because it is implicitly included in the \( \mathcal{B}(y) \) coefficient. This leads one to consider a modified form of (16) in which the \( G_{21} \tilde{x}_s^2 L \) term is included in the argument of the exponential, and subtracted after exponentiation. We refer to this as the 'modified R-matching' scheme (called 'intermediate' matching in [28], and R-matching in [21]). The coefficient \( G_{21} \) is not known analytically, but may be inferred approximately from numerical integration of the \( \mathcal{O}(\alpha_s^2) \) matrix elements. The relevant \( G_{nm} \) coefficients, insofar as they are known, are given in Table 3, based on
The value of \( y_{\text{max}} \) was taken to be 0.5 for \((1 - T)\), 0.42 for \( M_{T} \), 0.325 for \( B_{T} \), and 0.33 for \( B_{W} \). The actual kinematic limit depends on the number of partons in the final state.

A further problem is that the NLLA calculations are not guaranteed to satisfy the necessary constraints, \( R(y) = 1 \) and \( dR/dy \to 0 \), at the kinematic limit, \( y_{\text{max}} \), corresponding to the region of hard gluon emission. In consequence the combined NLLA + \( \mathcal{O}(\alpha_{s}^{2}) \) calculation may fit data less well than the \( \mathcal{O}(\alpha_{s}^{2}) \) expression in the hard region. It has been proposed [46, 21] that this difficulty could be overcome in the \( \ln(R) \)-matching scheme by replacing \( L \) in the NLLA part of (15) by \( L' = \ln(y^{-1} - y_{\text{max}}^{-1} + 1) \). We refer to this possibility as 'modified \( \ln(R) \)-matching'***.

All four matching schemes described above may be applied to the observables \((1 - T)\), \( M_{T} \), \( B_{T} \) and \( B_{W} \). The value of \( G_{22} \) is not known for \( R_{2} \), and cannot be estimated until a complete calculation of \( G_{22} \) is available, so the modified \( R \)-matching scheme is not applicable to \( R_{2} \). The \( \Sigma_{\text{EFC}} \) exhibits a particular problem because the \( \mathcal{O}(\alpha_{s}^{2}) \) differential distribution diverges at both small and large \( y \), so that the cumulative coefficients \( \mathcal{A} \) and \( \mathcal{B} \) cannot be reliably determined. This precludes the use of the \( \ln(R) \)- and modified \( \ln(R) \)-schemes for \( \Sigma_{\text{EFC}} \). However, the other matching schemes are applicable to the differential \( \Sigma_{\text{EFC}} \) distribution because they depend only on differences between values of \( \mathcal{A} \) and \( \mathcal{B} \) across a bin. It should also be noted that the coefficient \( C_{2} \) is not known for \( \Sigma_{\text{EFC}} \) nor for \( R_{2} \).

The situation is slightly different in the case of the average jet multiplicity \( \mathcal{N} \), since it cannot be written in the exponentiated form of (8). This calculation to \( \mathcal{O}(\alpha_{s}^{2}) \) gives a prediction of the form:

\[
\mathcal{N} = 2 + A(y) \tilde{a}_{s} + B(y) \tilde{a}_{s}^{2},
\]

and the NLLA calculation yields:

\[
\mathcal{N}_{\text{NLLA}} = 2 + \sum_{n=1}^{\infty} \mathcal{H}_{n}(L) \tilde{a}_{s}^{n};
\]

\[
\mathcal{H}_{1}(L) = H_{12} L^{2} + H_{11} L;
\]

\[
\mathcal{H}_{2}(L) = H_{24} L^{4} + H_{23} L^{3} + H_{22} L^{2}.
\]

The equivalent to the \( R \)-matching scheme is:

\[
\mathcal{N} = \mathcal{N}_{\text{NLLA}} - \mathcal{H}_{1}(L) \tilde{a}_{s} - \mathcal{H}_{2}(L) \tilde{a}_{s}^{2} + A(y) \tilde{a}_{s} + B(y) \tilde{a}_{s}^{2},
\]

while a procedure analogous to \( \ln(R) \)-matching is [47]:

\[
\mathcal{N} = \mathcal{N}_{\text{NLLA}} \exp \{ - \mathcal{H}_{1}(L) \tilde{a}_{s} - (\mathcal{H}_{2}(L)
\]

\[
- \frac{1}{2} \mathcal{H}_{1}(L) \tilde{a}_{s}^{2} + A(y) \tilde{a}_{s} + (B(y)
\]

\[
- \frac{1}{2} A(y)^{2} \tilde{a}_{s}^{2} \}.
\]

The coefficients \( H_{12}, H_{11}, H_{24} \) and \( H_{23} \) were contained in (8) of [27], and by expansion of the NLLA expressions in [27] one can obtain \( H_{22} = \frac{40}{6561} n_{f} (7 n_{f} - 27) \) [47].

A final consideration is the choice of renormalization scale. To \( \mathcal{O}(\alpha_{s}^{2}) \) the strong coupling constant may be written (following the convention of [48]):

\[
\alpha_{s}(\mu) = \frac{1}{\beta_{0} \ln(\mu^{2}/A_{MS}^{2})} \left[ 1 - \beta_{1} \ln(\ln(\mu^{2}/A_{MS}^{2})) \right],
\]

where \( \beta_{0} = (33 - 2 n_{f})/12 \pi, \beta_{1} = (153 - 19 n_{f})/24 \pi^{2} \) and \( n_{f} \) is the number of quark flavours, taken to be 5. The QCD scale \( A_{\text{MS}} \) refers to the MS renormalization scheme. One can relate the renormalization scale \( \mu \) to the \( e^{+}e^{-} \) centre of mass energy by

\[
\mu = x_{\mu} \cdot E_{\text{cm}},
\]

where \( x_{\mu} \) is the renormalization scale factor. Naïvely \( x_{\mu} \) would be expected to be of order unity. However, using \( \mathcal{O}(\alpha_{s}^{2}) \) QCD the experimental data for most observables tend to be better fitted with a value \( x_{\mu} \ll 1 \) (see e.g. [5]). This is generally understood to be a consequence of missing higher order terms in the \( \mathcal{O}(\alpha_{s}^{2}) \) approach, and it is therefore anticipated that the inclusion of higher order terms in the NLLA calculations should reduce the dependence on \( x_{\mu} \). In order to account for the dependence on \( x_{\mu} \), the above formulae have to be modified by the replacements [4, 21]:

\[
\mathcal{B}(y) \to \mathcal{B}(y) + \mathcal{A}(y) 2 \pi \beta_{0} \ln x_{\mu}^{2} \]

\[
g_{2}(\alpha_{s}, L) \to g_{2}(\alpha_{s}, L) + \beta_{0} \alpha_{s}^{2} L^{2} \frac{d g_{1}(\alpha_{s}, L)}{d(\alpha_{s}, L)} \ln x_{\mu}^{2} \]

\[
G_{22} \to G_{22} + 2 \pi \beta_{0} G_{11} \ln x_{\mu}^{2}.
\]

An equivalent procedure for \( \mathcal{N} \) [47] involves substituting throughout:

\[
\tilde{a}_{s} \to \tilde{a}_{s} + \tilde{a}_{s}^{2} 2 \pi \beta_{0} \ln x_{\mu}^{2}.
\]

### 4.2 Measurement of \( \alpha_{s}(M_{Z}) \)

After correcting the data to the parton level as outlined in Sect. 3.2, the NLLA + \( \mathcal{O}(\alpha_{s}^{2}) \) QCD calculations were fitted to the data using a least \( \chi^{2} \) method. For comparison

Only statistical errors on the data were included in the calculation of $\chi^2$ (including the effect of limited Monte Carlo statistics). Systematic uncertainties on the data (Sect. 4.3.1) were not taken into account in calculating $\chi^2$ since their definition is essentially arbitrary, and their correlations could not be estimated reliably. Nor were errors on the QCD coefficients taken into account. Fits were performed with the renormalization scale factor $x_u$ fixed to 1, and also with $x_u$ treated as an additional free parameter. When using a value $x_u \neq 1$ the fitted value of $A_{\bar{q}g}$ is converted into an equivalent value of $\alpha_s$ at scale $M_{Z\gamma}$ using (21); throughout the rest of this paper $\alpha_s$ should we also fitted the $\mathcal{O}(\alpha_s^2)$ QCD predictions. A number of considerations were taken into account in determining the range over which the data were to be fitted. We required that the detector and hadronization correction factors should be reasonably uniform across the fit range, and that the hadronization correction should not be strongly model dependent. This generally determined how far into the two-jet region ($y \to 0$) the NLLA fits could reliably be performed, and also set the upper limit on most of the $\mathcal{O}(\alpha_s^2)$ fits. We also required that the value of $\chi^2$ be "reasonable", in the sense that the contributions to $\chi^2$ should be distributed fairly evenly across the fit range, and not dominated by the extreme bins. Generally the lower limit for the $\mathcal{O}(\alpha_s^2)$ fits had to be placed higher (further from the two jet region) than for the NLLA fits, and in some cases the upper limit had to be placed lower for the NLLA fits than for the $\mathcal{O}(\alpha_s^2)$ fits (because the NLLA calculations do not necessarily fall off correctly toward the hard kinematic limit). A further constraint for $\Sigma_{EFC}$ was the presence of an unphysical pole introduced in the NLLA calculation [24], at around $\chi = 178^\circ$; the chosen fit range was well away from this point. The fit ranges chosen are given in Table 4. We confirmed that the results for $\alpha_s$ were not significantly altered if the fit range was moved by one or two bins (though in some cases the value of $\chi^2$ was significantly worse), and therefore no additional error was assigned resulting from possible uncertainties in the choice of fit range.

Fig. 2. Normalized cross sections $\frac{1}{\sigma} \frac{d\sigma}{dx}$, corrected to the parton level, where the observable $X$ is: a $(1 - T)$, b $M_H/\sqrt{s}$, c $B_r$, d $B_w$. The curves show the QCD fits using NLLA + $\mathcal{O}(\alpha_s^2)$ calculations combined with ln ($R$)-matching, at scale $x_u = 1$. The dotted lines indicate the fit ranges used
be taken to refer to $\alpha_s(M_Z)$. We used the $\ln(R)$-matching scheme to combine the NLLA and $\mathcal{O}(\alpha_s^2)$ calculations, except for $\Sigma_{EEC}$ where the modified $R$-matching scheme was used instead. The use of other matching schemes will be discussed in detail below. The fit results are listed in Table 5. The data corrected to the parton level are shown in Figs. 2 and 3, with the NLLA+$\mathcal{O}(\alpha_s^2)$ fits superimposed. The dependence of $\alpha_s$ and $\chi^2$/d.o.f on $x_u$ is shown in Fig. 4. The fits with $x_u = 1$ yield acceptable values of $\chi^2$/d.o.f. (less than 10 for all observables except $B_w$), though they are all greater than unity, as might be expected since the theory is known to lack some higher order terms, and also since experimental systematic errors have not been included at this stage. In the case of $M_H$, $B_w$ and $B_T$ the theory is seen to diverge from the data at high values; this arises because the NLLA calculations are not constrained to fall to zero at the upper kinematic limit; the introduction of the modified $\ln(R)$-matching scheme substantially reduces this problem. Five of the observables give very similar values of $\alpha_s$, while $B_w$ gives a rather lower value, and $\Sigma_{EEC}$ a higher result. In the fits where $x_u$ is treated as a free parameter, we find that only the jet broadening measures favour values of $x_u$ much smaller than one, while several observables yield a best fit with $x_u > 1$. The dependence of $\chi^2$/d.o.f. on $x_u$ is particularly weak for $(1 - T)$ and $R_2$, so that the fitted parameters are very poorly determined.

For comparison, Table 6 shows corresponding fit results using $\mathcal{O}(\alpha_s^2)$ QCD. The dependence of $\alpha_s$ and $\chi^2$/d.o.f on $x_u$ is shown in Fig. 5. Generally the $\mathcal{O}(\alpha_s^2)$ calculations give a significantly better $\chi^2$ when a value $x_u \approx 1$ is adopted, the only exception being $B_T$. This strong scale dependence is an indication of substantial missing higher order contributions. Comparing with the NLLA fit results in Table 5 we note that in several cases the inclusion of the NLLA terms in the QCD calculation improves the fit to the data for $x_u = 1$. However, the $\mathcal{O}(\alpha_s^2)$ fits with optimised scale generally yield values of $\chi^2$/d.o.f. as good as those obtained from the NLLA calculations. The most striking aspect of the NLLA fits is the elimination of the preference for very small $x_u$ values.

In Table 7 we show the effect of using different matching schemes to combine the NLLA and $\mathcal{O}(\alpha_s^2)$ calculations. As discussed above, and in [23], the $R$-matching scheme is theoretically less favoured, since it fails to exponentiate some terms which are exponentiated in the $\ln(R)$- or modified $R$-schemes. The fits to the data are poor in the $R$-scheme for $B_w$ and $B_T$ (for which the coefficient $G_{21}$ is particularly large), and to a lesser extent for $M_H$, $R_2$ and $N$. The modified $R$-scheme, in which the deficiencies of the naive $R$-scheme are remedied by exponentiating the $G_{21}$ term, yields results which are very close to the $\ln(R)$-scheme. The modified $\ln(R)$-scheme, in which correct behaviour of the NLLA calculations is enforced near the kinematic limit, gives a significantly improved fit to the data for $M_H$, $B_T$, and particularly $B_w$, though the value of $\alpha_s$ is scarcely affected. We therefore use the $\ln(R)$-matching scheme to obtain our standard results through this analysis, except for $\Sigma_{EEC}$, where the modified $R$-scheme is used instead.

Fig. 5. Dependence of \( \alpha_s(M_{Z^0}) \) (solid curves) and \( \chi^2/\text{d.o.f.} \) (dashed curves) on \( x_u \) for \( \mathcal{O}(a_s^2) \) fits to the OPAL data.

4.3 Estimation of systematic uncertainties

The values of \( \alpha_s(M_{Z^0}) \) for the seven observables together with their statistical errors are given in Table 8. Before a meaningful value of \( \alpha_s \) can be quoted it is necessary to investigate various possible sources of systematic uncertainty. With the present amount of data these systematic effects prove totally to dominate the small statistical errors. The systematic effects may be grouped under the following headings:

4.3.1 Experimental uncertainties. The corrections for detector acceptance and resolution depend upon the Monte Carlo simulation giving a faithful description of the real data. In our standard analysis both measured tracks and electromagnetic energy clusters were used. The analysis was repeated using tracks alone or the electromagnetic calorimetry alone, thus yielding samples of corrected data with completely independent detector corrections. The analysis was also repeated with several independent modifications to the event selection criteria: firstly restricting the thrust axis to lie within the barrel region of the detector (|\( \cos \theta \)| < 0.7), secondly increasing the minimum track multiplicity cut to 7 to eliminate background more securely, and finally using a cut on missing momentum (|\( \mathbf{p}_{\text{vis}} \)/\( E_{\text{vis}} \)| < 0.4), where \( \mathbf{p}_{\text{vis}} \) is the vector sum of all the detected particle momenta. Values of \( \alpha_s \) were computed from each of these alternative analyses and the...
The effect of these changes was generally found to be modest. Some of the parameters of the JETSET 7.3 model [43] have been investigated: corrections based on the full simulation of the OPAL specific related to hadronization, \( \alpha(21) \). This fit procedure yielded values of the parameters which are determined from a fit to OPAL data on global event shapes [42]. The analytic QCD calculations assume the partons are massless, and therefore predict the same distributions for any quark flavour. The parton shower Monte Carlo programs assign masses to the quarks, and indeed the parton level distributions exhibit some differences between heavy and light quarks for the observables considered here. We have therefore, in JETSET 7.3, investigated the effect of performing the hadronization correction by excluding \( bb \) events at the parton level, whilst including all flavours at the hadron level. In this way the corrected parton level distribution corresponds to \( u, d, s, c \) quarks only. The parton shower Monte Carlo programs incorporate a minimum value, \( Q_0 \), for the parton virtuality; for example \( Q_0 = 1 \) GeV in JETSET 7.3 with the OPAL parameter set. In contrast the NLLA calculations impose no such cutoff. We have therefore tried varying the value of \( Q_0 \) in JETSET between 4 GeV and the minimum value permitted (\( Q_0 = 2.2 \times A = 0.638 \) GeV). We find that, within this range, the value of \( \alpha_s \) derived from the data varies approximately linearly with the value of \( Q_0 \) used in the hadronization correction. We therefore take the difference between the values of \( \alpha_s \) corresponding to \( Q_0 = 1 \) GeV and \( Q_0 = 2 \) GeV as a (symmetric) systematic error resulting from this source; insofar as the linear ap-

### Table 8. Systematic errors on the value of \( \alpha_s(M_{Z^0}) \) derived from each of the seven observables. In all cases the NLLA + \( \sigma(\alpha_s^2) \) QCD calculations were fitted to the data assuming \( \alpha_s = 1 \). The \( \ln(R) \)-matching scheme was used except for \( \Sigma_{\text{REC}} \), where the modified \( R \)-scheme was taken. In the cases where a signed value is quoted, this indicates the direction in which \( \alpha_s(M_{Z^0}) \) changed with respect to the default analysis when a certain feature of the analysis was changed.

</table>
proximation is valid this would encompass the value \(Q_0 = 0\). As seen from Table 8, the value of \(\alpha_s\) is not strongly dependent on \(Q_0\).

- The HERWIG program [44] uses a cluster fragmentation model which is quite different from the string model [50] employed in JETSET. We have used version 5.5 of HERWIG, with parameters based on a tuning to OPAL event shape data [45]. In several cases, this constitutes the largest hadronization uncertainty in \(\alpha_s\), though the effect is not in the same direction for all observables.

- The ARIADNE model [51] uses a colour dipole formulation of the parton shower, with the standard Lund string model for hadronization. We used ARIADNE version 3.1 with parameters tuned to OPAL data [42]; in most cases the influence on \(\alpha_s\) is small.

- The COJETS model [52] uses an incoherent parton shower with independent fragmentation. We used version 6.23 with default parameters. However, the parton shower in this model does not evolve so far as in the other models considered (the average number of partons is 3.3, compared to 9.1 in JETSET). It therefore appears that COJETS, with its present parameters, is not appropriate at the parton level for comparison with the NLLA calculations, which implicitly incorporate multi-parton final states. For this reason, and for other reasons outlined in [5], we exclude COJETS from the final assignment of systematic errors, though we show the effect of using it in Table 8.

It is arguable that the hadronization effects listed above are not altogether independent (for example, JETSET and HERWIG use different effective cutoffs in the parton shower). However, none of the models is likely to be perfect, so in order not to underestimate this uncertainty we define a total hadronization error for each observable by adding in quadrature the following: the larger of the changes in \(\alpha_s\) when \(x_e\) is changed by \(+1\) and \(-1\) standard deviation, the larger of the changes in \(\alpha_s\) when \(\sigma_g\) is changed by \(+1\) and \(-1\) standard deviation, the change in \(\alpha_s\) when only \(u, d, s, c\) quarks are considered in JETSET, the change in \(\alpha_s\) when Peterson fragmentation is used in JETSET, the change in \(\alpha_s\) when \(Q_0 = 2\) GeV is used in JETSET, the change in \(\alpha_s\) when HERWIG is used and the change in \(\alpha_s\) when ARIADNE is used. This total error is given in Table 8. It appears that the single hemisphere variables, \(B_w\) and \(M_H\), are the least sensitive to hadronization, while \(B_T\) is the most sensitive of the observables considered here.

4.3.3 Renormalization scale uncertainties. The choice of the value of \(x_e\) is a significant source of systematic uncertainty, but the precise way to quantify this error is essentially arbitrary. This uncertainty is generally understood to be connected with higher order contributions missing from the QCD calculations. In our previous \(\mathcal{O}(\alpha_s^4)\) analysis [5] we discussed various procedures to define \(x_e\), but finally chose to average the values of \(\alpha_s(M_Z)\) obtained with \(x_e = 1\) and with \(x_e\) fitted to data, and to quote half their difference as a systematic error. However, this procedure does not seem appropriate for the present NLLA + \(\mathcal{O}(\alpha_s^2)\) analysis. In some cases the optimal fitted value of \(x_e\) is close to 1, in which case the previous method would underestimate the scale uncertainty. Furthermore, in some cases \(\chi^2\) does not show a well defined minimum, falling slowly but monotonically with increasing \(x_e\). We therefore choose to define the scale uncertainty to be the variation in \(\alpha_s(M_Z)\) as the renormalization scale factor is varied in the range \(0.5 < x_e < 2\). The case \(x_e = 1\) is taken to be the central value, so the scale error is asymmetric in general.

4.3.4 Matching scheme uncertainties. Different matching schemes were discussed in Sect. 4.1; they are equivalent so far as the leading and next-to-leading terms are concerned, but differ in the higher order terms generated by exponentiation. Therefore the differences between the results in Table 7 represent a further measure of possible higher order effects. In those cases where more than two matching schemes were available, we observe that all the matching procedures except for the \(R\)-scheme yield very similar values of \(\alpha_s\). Since the \(R\)-scheme is disfavoured both theoretically, and in many cases by the \(\chi^2/d.o.f.\) values of the fits, we choose to discount it. The remaining uncertainty in \(\alpha_s\) resulting from different matching procedures is much smaller than the error already assigned on the basis of \(x_e\) dependence. Since the two effects may be expected to be correlated because both relate to missing higher orders, we assign no additional error resulting from the choice of matching scheme.

4.3.5 Explicit inclusion of subleading logarithms. As a final check of possible higher order effects, we have investigated the possibility of including a subleading logarithmic term in the fit. In the case of \((1 - T), M_H, B_T, B_w\) and \(\Sigma_{EFC}\), and for all matching schemes except \(R\)-matching, the leading and next-to-leading logarithms and the subleading term \(G_{32} \tilde{z} L^2\) are all resummed, and hence the first subleading logarithmic term to be absent from the resummation is \(G_{32} \tilde{z} L^2\). We have therefore performed fits to the data including a term of this form in the exponentiation, treating \(G_{32}\) as a free parameter to be determined in the fit. The results are summarized in Table 9. The values of \(\chi^2/d.o.f.\) are substantially improved by the inclusion of the subleading term, suggesting that higher order effects might in large part account for the values of \(\chi^2/d.o.f.\) in the standard analysis being greater than unity. The fitted values of \(G_{32}\) are different for different matching schemes, indicating that this term is effectively parametrizing a mixture of higher order terms. Naively one might guess that the values of \(G_{32}\) could be greater than \(G_{21}\) by a factor of order \(2\pi\) (since a factor \((2\pi)^{-1}\) appears in \(\tilde{z}\)), and the fitted values are therefore not of unreasonable size. By reference to Table 5, we note that varying \(G_{32}\) in the fits yields better \(\chi^2/d.o.f.\) values than varying \(\tilde{z}\). Also the values of \(\alpha_s\) for the different variables tend to move slightly closer together when \(G_{32}\) is fitted, in contrast to their behaviour when \(\tilde{z}\) is fitted. The most important feature is that the changes in the fitted values of \(\alpha_s\) when \(G_{32}\) is fitted are small, and contained within the errors already assigned from the study of \(x_e\) dependence. We therefore assign no additional systematic error as a result of this study.
Table 9. Values of $\alpha_s(M_{Z^0})$ and $\chi^2$/d.o.f. derived by fitting the NLLA + $\mathcal{O}(\alpha_s^2)$ QCD calculations to the data, for $x_F = 1$, allowing the subleading coefficient $G_{32}$ to be determined in the fit

4.3.6 Final errors on $\alpha_s(M_{Z^0})$. Finally, the statistical error, the experimental systematic uncertainty, the hadronization error, and the scale uncertainty are all combined in quadrature to yield the errors given in the final row of Table 8. The values are also shown in Fig. 6. If only experimental errors are taken into account, the results (in particular those from $B_W$ and $\Sigma_{EEC}$) are not compatible with a common value, especially if correlations between the systematic contributions are taken into consideration. If the full systematic errors are considered then there appears to be no inconsistency, but again the observables are not fully independent, as discussed below.

4.4 Combined result

A particular emphasis of this analysis was to study all the observables for which resummed QCD calculations are available. It is therefore instructive to combine the measurements of $\alpha_s$ from the seven variables considered in this analysis, in order to assess the degree of consistency with which QCD describes the data, and in order to arrive at a "best estimate" of $\alpha_s(M_{Z^0})$. We have considered three methods:

4.4.1 Weighted mean. This method is essentially identical to that employed in the previous OPAL paper [5]. A weighted mean was formed:

$$\bar{\alpha}_s = \frac{\sum_{i=1}^{7} w_i \alpha_s^{(i)}}{\sum_{i=1}^{7} w_i}$$

where $\alpha_s^{(i)}$ is the value of $\alpha_s$ derived from the $i^{th}$ observable, and the weight $w_i$ is equal to the reciprocal of the square of the total error on $\alpha_s^{(i)}$ as given in Table 8. In order to estimate the error on the weighted mean statistical correlations between the different observables were ignored, but correlations in the systematic uncertainties were taken into account by forming the mean $\bar{\alpha}_s$ of the values obtained in each of the different systematic checks described in Sect. 4.3. A systematic uncertainty on $\bar{\alpha}_s$ was then derived from the different mean values following the same procedure as for the individual $\alpha_s^{(i)}$ measurements.

Applying this procedure to all seven observables we obtain the value:

$$\alpha_s(M_{Z^0}) = 0.120 \pm 0.003 \text{ (expt.)} + 0.006 \text{ (theor.)} - 0.004 \text{ (theor.)}$$

where the first error includes statistical and experimental systematic effects, while the second includes the hadronization and scale uncertainties. If the $B_W$ variable, which gave a rather low value of $\alpha_s$, and also the smallest overall error, were excluded the mean would increase to 0.123, if $\Sigma_{EEC}$ were excluded the mean would be 0.118, while if both were removed the mean would be 0.121.

The NLLA calculations are arguably less reliable for $\Sigma_{EEC}$ (an unphysical pole is introduced in the calculation, though well outside the fit region) and for the jet rates.
(the next-to-leading resummation is incomplete); if we were to average the other observables, \((1 - T), M_H, B_T\) and \(B_{\mu^+}\), we would obtain 0.116. Thus the overall mean of all seven observables yields a value and an error which comfortably encompasses the mean of any reasonable subset.

4.4.2 Minimization of \(\chi^2\). In order to account for the correlation between observables in a more formal way, we have estimated the value \(a_s\), which is most consistent with all the measurements, by minimizing

\[
\chi^2 = \sum_{i=1}^{7} \sum_{j=1}^{7} (\hat{a}_s - a_s^0) (\mathcal{Y}^{-1})_{ij} (\hat{a}_s - a_s^0)
\]

with respect to \(\hat{a}_s\), where \(\mathcal{Y}\) is the covariance matrix of the seven individual measurements. The statistical part of \(\mathcal{Y}\) was estimated by dividing the data and Monte Carlo samples into ten subsamples, determining values of \(a_s^0\) from each, and measuring the covariances between them. Thus was added a matrix associated with each of the detector and hadronization systematic effects listed in Sect. 4.3.* Following this procedure for the case \(x_\mu = 1\) we find an unacceptable value of \(\chi^2/d.o.f. = 34\), with a value of \(\hat{a}_s = 0.113\) which lies below most of the measurements on account of strong positive correlations between the systematic errors. The large value of \(\chi^2/d.o.f.\) is associated with \(\Sigma_{EBC}\), and to a lesser extent \(B_{\mu^+}\); restricting the procedure to the other five observables we could obtain \(\chi^2/d.o.f. = 0.3\) and \(\hat{a}_s = 0.121\), showing that these five are very compatible.

Thus the NLLA + \(\mathcal{O}(a_s^2)\) theory appears to be unable to describe \(\Sigma_{EBC}\) and \(B_{\mu^+}\) simultaneously with the other five variables, if the systematic errors and their correlations are estimated as described above, and if the value of \(x_\mu\) is fixed to the same value for all observables. However, if the scale error given in Table 8 is included in the diagonal terms of \(\mathcal{Y}\) then a satisfactory value of \(\chi^2/d.o.f. = 1.7\) may be obtained using all seven observables, with \(\hat{a}_s = 0.119 \pm 0.004\), in agreement with the weighted mean in Sect. 4.4.1. This procedure effectively allows the \(a_s\) value corresponding to each observable to vary independently by an amount corresponding to the range \(0.5 < x_\mu < 2\). However, it does not address the extent to which the \(\chi^2/d.o.f.\) of the fit to the data depends on \(x_\mu\); this is considered in the next section.

4.4.3 Combined fit. In a previous OPAL paper [5] we introduced a method for investigating the consistency of QCD by performing a simultaneous fit to the distributions of many observables using a common value of \(A_{\overline{\text{MS}}}\). In the case of \(\mathcal{O}(a_s^2)\) QCD we found that such a simultaneous fit could be successful, but only if the renormalization scale factor, \(x_\mu\), was allowed to vary independently for each observable, most of the fitted values of \(x_\mu\) being much smaller than unity.

Accordingly we have attempted a similar fit of NLLA + \(\mathcal{O}(a_s^2)\) QCD to the present data. The same fit ranges were used as for the standard fits, but in order that each observable carry equal weight in the fit, bins in the data were combined so as to form an equal number of bins, seven for each observable. Correlations between the errors on different observables were neglected. As usual, the \(\ln(R)\)-matching scheme was used except for \(\Sigma_{EBC}\), where the modified \(R\)-scheme was taken. The result of a combined fit to all seven observables with \(x_\mu = 1\) was \(a_s = 0.122\), in good agreement with the weighted mean described in Sect. 4.4.1. However, the combined fitting gave an unacceptable value of \(\chi^2/d.o.f. = 93\), some ten times greater than expected from the sum of the \(\chi^2\) values of the separate fits. This large value of \(\chi^2\) was mainly contributed by the \(\Sigma_{EBC}\) and \(B_{\mu^+}\) variables; if these two were removed a combined fit to the remaining five variables yielded \(a_s = 0.121\) with \(\chi^2/d.o.f. = 8.8\). The procedure of allowing the \(x_\mu\) values to vary is not so obviously reasonable in the NLLA case as in the \(\mathcal{O}(a_s^2)\) analysis. Nevertheless, if such a fit is performed, an acceptable \(\chi^2\) may be achieved with all seven observables, but with a large value \(a_s = 0.143\) and \(x_\mu \gg 1\) for all observables. This seems to be needed in order to accommodate \(\Sigma_{EBC}\), where a reduction of \(a_s\) to around 0.120 would lead to a large increase in \(\chi^2/d.o.f.\). A fit to the remaining six observables with \(x_\mu\) free gives \(a_s = 0.121\), with \(\chi^2/d.o.f. = 7.7\) and all \(x_\mu\) values in the vicinity of unity. Alternatively, a fit to all seven observables, but using the \(R\)-matching scheme for \(\Sigma_{EBC}\) yields \(a_s = 0.124\) with \(\chi^2/d.o.f. = 7.9\) and \(x_\mu\) values close to unity. Similar results may be obtained from a combined fit (excluding \(R_2\) and \(A\)) in which \(x_\mu\) is fixed to 1 while the subleading coefficient \(G_{12}\) is allowed to vary independently for each observable.

Thus, these combined fits indicate that, given the presently available calculations, \(\Sigma_{EBC}\); and to a lesser extent \(B_{\mu^+}\), cannot be described by NLLA + \(\mathcal{O}(a_s^2)\) QCD simultaneously with the other observables, particularly if \(x_\mu = 1\) is assumed. Nonetheless, an average value of \(a_s(M_{Z^0})\) around 0.120 seems quite reliable.

5 Discussion and summary

Resummed QCD calculations have been introduced in an attempt to describe the two-jet region in \(e^+e^-\) hadronic final states. In this region the previously available \(\mathcal{O}(a_s^2)\) QCD matrix elements were clearly insufficient because of the presence of large logarithms connected with soft and collinear singularities. Resummed calculations are now available for seven observables, which we have studied in this analysis. Two of the observables, \(B_T\) and \(B_{\mu^+}\), had not been studied in \(e^+e^-\) annihilation before the calculations were performed, and therefore constitute a new test of the theory. Although jet rates have been extensively studied before, the Durham jet finder is comparatively new and measurements for \(R_2\) and \(A\) were not available before the calculations. The calculations should be most secure for \((1 - T), M_H, B_T\) and \(B_{\mu^+}\), for which complete resummation of leading and next-
to-leading logarithms was done. For the jet rates only part of the next-to-leading logarithms were resummed, while the analytic solution of the $\Sigma_{\text{REC}}$ calculation in [24] introduced an unphysical pole which limits the region of applicability of the theory.

Comparison of the theory with data in Figs. 2 and 3 shows that a good qualitative description of the data in the two-jet region is obtained. However, in this region the corrections which relate the observed hadron level to the parton level where the QCD calculations are relevant are, at present energies, large and subject to significant uncertainties. We have therefore chosen to combine the NLLA and $\mathcal{O}(\alpha_s^2)$ calculations, and fit to data in the region where the hadronization corrections are reasonably small and reliable. However, in the more extreme hard region the higher order contributions which are absent from the $\mathcal{O}(\alpha_s^2)$ theory are not necessarily dominated by the leading logarithms which we include in the present approach, and the leading logarithmic terms could even have an opposite sign from the uncomputed higher orders. Thus in this region the inclusion of the NLLA terms could even degrade the description of data, as seen particularly for $M_H$ and $B_W$ in Fig. 2.

The NLLA + $\mathcal{O}(\alpha_s^2)$ QCD calculations, with renormalization scale factor $x_\mu = 1$, were found to give reasonable fits to the OPAL data. In some cases the fits were better than those obtained using $\mathcal{O}(\alpha_s^2)$ QCD alone with $x_\mu = 1$, though no better than $\mathcal{O}(\alpha_s^2)$ fits with optimized scale. However, the $\mathcal{O}(\alpha_s^2)$ fits where $x_\mu$ was optimized generally yielded values $x_\mu < 0.1$, whilst such low values of $x_\mu$ were clearly disfavoured by the NLLA + $\mathcal{O}(\alpha_s^2)$ calculations. The dependence of $\alpha_s(M_{Z^0})$ on the choice of $x_\mu$ was slightly weaker when the resummed theory was included, but still remained the principal source of systematic uncertainty.

Table 10 shows the final results for $\alpha_s(M_{Z^0})$ obtained from each of the seven observables using NLLA + $\mathcal{O}(\alpha_s^2)$ QCD, with the corresponding results obtained from the same data using $\mathcal{O}(\alpha_s^2)$ QCD alone for comparison. The experimental errors were essentially the same for both approaches, and the same as in our previous publication [5]. The hadronization uncertainties were estimated in the same way for both sets of measurements, though a larger range of hadronization models was considered than in our previous paper [5]. As in our previous work a wider variation of $1 < Q_0 < 6$ GeV was considered for the $\mathcal{O}(\alpha_s^2)$ analysis. The principal difference between the NLLA and $\mathcal{O}(\alpha_s^2)$ analyses was however the treatment of the renormalization scale uncertainty; in the NLLA + $\mathcal{O}(\alpha_s^2)$ case we took $x_\mu = 1$ as the central value, assigning an error by considering the range $0.5 < x_\mu < 2$, while in the $\mathcal{O}(\alpha_s^2)$ analysis we followed our procedure in [5], taking the central value to be the mean of the values of $\alpha_s(M_{Z^0})$ from $x_\mu = 1$ and $x_\mu$ fitted, and quoting half their difference as the error. Figures 6 and 7 show the values of $\alpha_s$ so obtained, together with their weighted means.

Neither the $\mathcal{O}(\alpha_s^2)$ nor the NLLA + $\mathcal{O}(\alpha_s^2)$ calculations give a consistent description of the data with $x_\mu = 1$ if only experimental errors are taken into account. After making due allowance for systematic uncertainties the $\mathcal{O}(\alpha_s^2)$ measurements are compatible with a common mean value of $0.122 \pm 0.007$. These conclusions are consistent with our previous study of thirteen observables to $\mathcal{O}(\alpha_s^2)$ [5], only three of which ($T$, $M_H$ and $R_2$) are shared with the present study. The value obtained here is very
measurements are compatible with a common mean of $\alpha_s$ (NLLA + $\mathcal{O}(\alpha^2_s)$ analysis), we find that the individual measurements are compatible with a common mean of $0.120 \pm 0.006$, which is in excellent agreement with the $\mathcal{O}(\alpha^2_s)$ analysis. However, because the systematic uncertainties are correlated it is not clear that the values of $\alpha_s$ obtained from the $B_W$ and $\Sigma_{\text{ECC}}$ variables are really compatible with this value. The case of $B_W$ is somewhat disappointing, since this variable has the smallest overall error, with a particularly weak hadronization uncertainty. Nonetheless, the values derived from $B_W$ and $\Sigma_{\text{ECC}}$ lie within two standard deviations of the weighted mean, which therefore seems a reasonable estimate of $\alpha_s$. In the $\mathcal{O}(\alpha^2_s)$ analysis the $B_W$ and $\Sigma_{\text{ECC}}$ observables exhibit no anomalous behaviour.

In previous measurements of $\alpha_s$ based on $\mathcal{O}(\alpha^2_s)$ QCD the main uncertainty was the effect of missing higher order terms, manifested particularly in the renormalization scale dependence. In the present study the NLLA calculations have been used to supplement the $\mathcal{O}(\alpha^2_s)$ theory with some higher order information. However, the NLLA + $\mathcal{O}(\alpha^2_s)$ calculations have not brought about a dramatic reduction in the error on $\alpha_s$. This is partly because the observables which showed the smallest scale dependence in $\mathcal{O}(\alpha^2_s)$ (such as the asymmetry in the EEC or the jet mass difference) have not so far proved amenable to resummation. Nevertheless, the inclusion of the NLLA terms has removed the need to consider very small renormalization scales; indeed the data are incompatible with such scales. After investigating several ways to combine the measurements of $\alpha_s$ we quote as our final result that based on a simple weighted average:

$$\alpha_s(M_Z) = 0.120 \pm 0.006.$$ 

The error is competitive with, but marginally larger than that obtained in our previous $\mathcal{O}(\alpha^2_s)$ measurement [5]. It also agrees well with the NLLA + $\mathcal{O}(\alpha^2_s)$ measurement in [5], and with other measurements of $\alpha_s$ at LEP and elsewhere, summarized in [18]. The error is however slightly smaller than that resulting from an $\mathcal{O}(\alpha^2_s)$ analysis performed on the present data. This new result based on NLLA + $\mathcal{O}(\alpha^2_s)$ QCD is therefore an important measurement, complementary to those obtained from $\mathcal{O}(\alpha^2_s)$ QCD; the fact that they are in such good agreement gives us confidence that higher order uncertainties are under control at the level of the errors which we quote.

Acknowledgements. We thank S. Catani, G. Turnock and B.R. Webber for many enlightening discussions and useful suggestions concerning parts of this analysis. It is a pleasure to thank the SL Division for the efficient operation of the LEP accelerator, the precise information on the absolute energy, and their continuing close cooperation with our experimental group. In addition to the support staff at our own institutions we are pleased to acknowledge the Department of Energy, USA; National Science Foundation, USA; Texas National Research Laboratory Commission, USA; Science and Engineering Research Council, UK; Natural Sciences and Engineering Research Council, Canada; Fussefeld Foundation; Israeli Ministry of Energy; Israeli Ministry of Science; Mi-
