Measurement of the $\tau^+ \to e^+ \bar{\nu}_e \nu_\tau$ branching ratio

OPAL Collaboration

Abstract

The branching ratio of the $\tau^- \rightarrow e^- \nu_e \bar{\nu}_e \nu_\tau$ decay mode has been measured with the OPAL detector to be $(17.78 \pm 0.10 \pm 0.09)\%$ where the first error is statistical and the second is systematic. The branching ratio, together with other measurements, has been used to test $e^- \mu$ and $\mu^- \tau$ universality in the charged current weak interaction.

1. Introduction

The $\tau^- \rightarrow e^- \nu_e \bar{\nu}_e \nu_\tau$ decay is a useful probe of the Standard Model. The branching ratio, in conjunction with other measurements, can be used to determine the relative charged current couplings of the electron, muon and tau leptons. In addition, it can be used to calculate $\alpha_s$ at $Q^2 = M_Z^2$, which can be compared with other measurements taken at $Q^2 = M_Z^2$. This letter reports on an update of the $\tau^- \rightarrow e^- \nu_e \bar{\nu}_e \nu_\tau$ branching ratio using the data collected between 1991 and 1994 with the OPAL detector at LEP.

The data were recorded using the OPAL detector which is a general purpose detector covering the full solid angle [1]. The tau pair Monte Carlo sample was generated using the KORALZ 4.0 package [2]. The dynamics of the tau decays were simulated with the TAUOLA 2.0 decay library [3]. The Monte Carlo events were then passed through the GEANT simulation [4] of the OPAL detector [5].

2. Selection of $\tau^+ \tau^-$ events

The procedure used to select $Z^0 \rightarrow \tau^+ \tau^-$ events is similar to that described in previous OPAL publications [6–8]. The decay of the $Z^0$ produces two back-to-back taus. The taus are highly relativistic so that the decay products are strongly collimated. As a result it is convenient to treat each tau decay as a jet, as defined in Ref. [9], where charged tracks and clusters in the lead-glass electromagnetic calorimeter are assigned to cones of half-angle $35^\circ$. The definitions of a charged track and electromagnetic cluster are also given in Refs. [6–8]. The tau pair selection requires that the event contains exactly two jets each with at least one charged track. The total electromagnetic energy plus the sum of the scalar momentum of the charged tracks in each jet must exceed 1% of the beam energy. The average value of $|\cos \theta|$ for the two charged jets must satisfy $|\cos \theta| < 0.68$, where $\theta$ is the polar angle.

The background in the $\tau^+ \tau^-$ sample includes contributions from the $e^+e^- \rightarrow e^+e^-$ [10], $e^+e^- \rightarrow \mu^+\mu^-$ [2], $e^+e^- \rightarrow q\bar{q}$ [11] and $e^+e^- \rightarrow (e^+e^-)X$ [12] reactions. The background from $e^+e^- \rightarrow e^+e^-$ is reduced by requiring the tau pair candidates to satisfy either $E_{\text{cluster}} \leq 0.8E_{\text{CM}}$ or $E_{\text{cluster}} + 0.3E_{\text{track}} \leq 0.8E_{\text{CM}}$.
The fiducial selection requires that the candidate jet have between 1 and 3 charged tracks. Regions of the detector where the z-measuring tracking chamber or ‘z-chamber’ 4 was not active and the regions of poor energy resolution in the electromagnetic calorimeter are eliminated. Also, we apply additional requirements to the tracks. The highest momentum track in each jet, assumed to be the electron candidate, must have hits in the z-chambers in order to improve the polar angular resolution. In addition, we require that each track have at least 40 hits in the central drift chamber that can be used in the measurement of the energy loss (dE/dx).

The efficiencies for the fiducial selection were determined using the entire tau data sample and are given in Table 2. Note that the efficiencies for the z-chamber and dE/dx-hits used in the branching ratio calculation were determined as a function of momentum but only average values are given in Table 2. The z-chamber and dE/dx hit efficiencies for jets with 1 charged track were tested to see if they were independent of the particle type using control samples of electron data. The systematic errors quoted on these efficiencies (see Table 2) represents the precision with which this assumption was tested.

The electron identification selection identifies the electron candidates out of the tau sample remaining after the fiducial selection. The electron identification selection relies on a relatively small set of variables in order to achieve high efficiency with low background. A number of the variables have been transformed into normalized quantities, $N'_V \equiv (V_{\text{measured}} - V_{\text{expected}}) / \sigma_V$, where $V_{\text{measured}}$ is the variable of interest. $V_{\text{expected}}$ is

---

4 A right-handed coordinate system is adopted in OPAL, where the x axis points to the centre of the LEP ring, and positive z is along the electron beam direction. The angles $\theta$ and $\phi$ are the polar and azimuthal angles, respectively.
The main variables used in the electron selection are plotted: (a) the normalized $dE/dx$, (b) the normalized $E/p$. (c) the normalized $\Delta\theta$, (d) the normalized $\Delta\phi$, (e) the number of clusters not associated to a charged track and (f) the number of hadron calorimeter layers. The data are represented by points and the Monte Carlo prediction is represented by the unshaded histogram. The shaded region of the histogram is the Monte Carlo prediction for the background. The data shown in each plot are required to pass the electron selection except for the variable displayed. The arrows indicate the regions accepted in the selection.

(a) Here we give the average efficiency whereas in the actual selection the momentum dependent efficiency is used.

The electron candidates are required to pass the following criteria:

(a) The charged track must have a $dE/dx$ measurement ($N^\sigma_{dE/dx} \geq -3$) compatible with that expected from an electron (see Fig. 1(a)).

(b) The energy of the cluster ($E$) associated to the track divided by the momentum of the track ($p$) must be close to unity (equivalently $N^\sigma_{E/p} \geq -4$ as shown in Fig. 1(b)).

(c) The difference in the position of the track and associated cluster is required to be less than a few milliradians. This is achieved by placing re-
quirements on the $N_{\Delta z}$ and $N_{\Delta \theta}$ distributions (see Figs. 1(c) and (d)), where $\Delta \theta = \theta_{tk} - \theta_{cl}$ and $\Delta \phi = \phi_{tk} - \phi_{cl}$. The matching in $\phi$ is complicated by the magnetic field and by photon radiation, so a looser matching criterion is applied in $\phi$ than in $\theta$.

(d) We require that there are less than two photons in the jet (see Fig. 1(e)). A cluster is considered a photon candidate if its energy is greater than 0.7 GeV and it is not associated to a charged track.

(c) We require that the electron candidate penetrate no further than 2 layers (0.6 interaction lengths) into the hadron calorimeter (see Fig. 1(f)).

(f) Residual $e^+e^- \rightarrow e^+e^-$ background is reduced by requiring that $\theta_{acop} > 0.002$ radians if both $p > 30$ GeV/c and $p_{opp} > 0.75E_{beam}$, where $\theta_{acop}$ is the acoplanarity angle in the plane transverse to the beam between the highest momentum tracks in each jet, $p$ is the momentum of the electron candidate, $p_{opp}$ is the momentum of the track in the jet opposite the electron candidate and $E_{beam}$ is the beam energy.

(g) If the jet contains 2 or 3 charged tracks, then we assume that highest momentum track is the electron. In order for the event to be considered an electron candidate, simple cuts are applied to the remaining track(s) to ensure that they are consistent with coming from a photon conversion.

4. Branching ratio determination

A total of 25,337 candidates pass the electron selection with an electron identification efficiency, $\epsilon_E$, of 0.9893 ± 0.0027 and a background, $f_{\text{bkgd}}^{\text{non}-e}$, of 0.0496 ± 0.0031. These results give a branching ratio of the $\tau^- \rightarrow e^-\nu_e\bar{\nu}_e$ decay of (17.78 ± 0.10(stat.) ± 0.09(syst.))%. The branching ratio was calculated using

\[
B_e = \frac{N_{\tau}^{\text{corr}}}{N_{\tau}(1 - f_{\text{bkgd}}^{\text{non}-e})} \frac{1 - f_{\text{bkgd}}^{\text{non}-e}}{\epsilon_E F_{\text{bias}}} \frac{1}{F_{\text{bias}}}
\]

where $N_{\tau}$ is the number of taus (165,616), $f_{\text{bkgd}}^{\text{non}-e}$ is the background in the tau sample (0.0170 ± 0.0012) and $F_{\text{bias}}$ is a correction for the slight bias on the branching ratio introduced by the tau pair selection.

5. Systematic uncertainties

The contributions to the systematic error are given in Table 3. The uncertainty in the efficiency of the electron selection and the uncertainty in the background in the electron sample are discussed in the following paragraphs. The photon conversion systematic error arises as the Monte Carlo has a slightly different probability for a photon conversion from that observed in the data. However since jets with up to three charged tracks are permitted into the sample, the dependence of the final result on this probability was found to be fairly weak.

The electron identification efficiency was determined using Monte Carlo. To test the validity of the Monte Carlo, the efficiency of each criterion in the selection was determined using highly pure control samples of electrons obtained by applying tight cuts to the tau sample. Comparisons of the efficiencies

(1.0036 ± 0.0022). The number of electrons, $N_{\tau}^{\text{corr}}$, in the above equation is corrected for the fiducial selection efficiencies (given in Table 2) by

\[
N_{\tau}^{\text{corr}} = \sum_{i=1}^{10} \frac{N_{\tau}^{\text{corr}}(i)}{\epsilon_F^{(i)} + \epsilon_E^{(i)} + \epsilon_f^{(i)}}
\]

where $N_{\tau}$ is the number of electron candidates and $\epsilon_F$ is the fiducial selection efficiency. The superscripts indicate the number of charged tracks in the jet. The summation is performed over 10 momentum bins for jets with 1 charged track. The average fiducial selection efficiency for jets with 1 charged track is 0.8395 ± 0.0020 where the error is dominated by the systematic error in the $z$-chamber hit efficiency. Using the average efficiencies will give a branching ratio similar to the quoted value.
obtained from the Monte Carlo and data control samples showed no inconsistencies. For example, we found the efficiency of the $dE/dx$ criterion to be $0.99562 \pm 0.00126$ and $0.99662 \pm 0.00102$ in the data and Monte Carlo, respectively. Since the efficiencies from the data and Monte Carlo were in good agreement, we assign a systematic error to the electron identification efficiency of 0.0016 for the $dE/dx$ requirement which is obtained by adding in quadrature the statistical errors of the data and Monte Carlo efficiencies. This procedure was repeated for each criterion and the total uncertainty on the electron identification selection efficiency is estimated to be 0.00048 (see Table 3). Additional checks were made using samples of $e^+e^- \rightarrow e^+e^-$ and $e^+e^- \rightarrow (e^+e^-)_{t} e^-$ data. Further, the reliability of the branching ratio was investigated by varying the individual selection requirements. No discrepancies were observed, so no additional uncertainty was added to the efficiency.

The background in the $\tau^- \rightarrow e^- \nu_e \nu_{\tau}$ sample is...
described below and presented in Table 1. The backgrounds were first estimated using Monte Carlo samples. The modelling of each of the backgrounds by the Monte Carlo was checked by creating subsamples from the electron candidates enriched in the background.

(a) \( \tau^- \rightarrow h^- \nu_\tau \). The \( \tau^- \rightarrow h^- \nu_\tau \) background was checked by comparing the \( N_{E/\mu}^o \) distribution for data and Monte Carlo (see Fig. 2(b)) for events that passed the electron selection but with the dE/dx requirement reversed so that hadrons instead of electrons were selected. We use the region \(-4 \leq N_{E/\mu}^o \leq 0\), which corresponds to the region included in our selection, to obtain a correction factor of \( 1.25 \pm 0.14 \).

(b) \( \tau^- \rightarrow e^- \nu_e \). The \( \tau^- \rightarrow e^- \nu_e \) branch was measured by OPAL to be \( (18.04 \pm 0.33)\% \) [8] using data collected between 1990 and 1992. The current result, \( (17.78 \pm 0.10 \pm 0.09)\% \), is consistent with the previous work, using a quite different selection procedure and with approximately three times the data sample. In addition, the branching ratio is consistent with other results, including recent measurements by ALEPH [13] of \( (17.79 \pm 0.12 \pm 0.06)\% \) and DELPHI [14] of \( (17.51 \pm 0.39)\% \). The 1994 Particle Data Group average value is \( (17.90 \pm 0.17)\% \) [15].

The \( \tau^- \rightarrow e^- \bar{\nu}_e \nu_\tau \) branching ratio can be used to test lepton universality. The ratio of the widths for \( \tau^- \rightarrow \mu^- \bar{\nu}_\mu \nu_\tau \) and \( \tau^- \rightarrow e^- \bar{\nu}_e \nu_\tau \) gives a measure of \( g_{\mu}/g_e \) [16]

\[
\frac{\Gamma(\tau^- \rightarrow \mu^- \bar{\nu}_\mu \nu_\tau)}{\Gamma(\tau^- \rightarrow e^- \bar{\nu}_e \nu_\tau)} = \frac{g^2_\mu}{g^2_e} \frac{f(m^2_\mu/M^2_e)}{f(m^2_e/M^2_\mu)}
\]

where \( g_{\mu} \) and \( g_e \) are the electroweak coupling constants for the muon and electron, and \( f(x) = 1 - 8x + 8x^3 - x^4 - 12x^2 \ln x \). Using the latest measurement of the \( \tau \) mass by the BES Collaboration of \( 1776.96^{+0.18+0.15}_{-0.21+0.17} \) MeV/c\(^2\) [17] and the OPAL \( \tau^- \rightarrow \mu^- \bar{\nu}_\mu \nu_\tau \) branching ratio of \( (17.36 \pm 0.27)\% \) [8], we obtain \( g_{\mu}/g_e = 1.0016 \pm 0.0087 \). Note, however, that the most precise test of this universality (at the level of 0.002) has been made by measuring the pion leptonic branching ratios [18].

A test of muon-tau universality can be made by comparing the partial widths for the \( \tau^- \rightarrow e^- \bar{\nu}_e \nu_\tau \) and \( \mu^- \rightarrow e^- \bar{\nu}_e \nu_\mu \) decays, which have the form [16]

\[
\frac{g^2_\mu}{g^2_e} = 0.9996 \frac{\tau_\mu m^5_e}{\tau_\tau m^5_e} B(\tau^- \rightarrow e^- \bar{\nu}_e \nu_\tau)
\]

Using the OPAL tau lifetime measurement of \( 288.8 \pm 2.2 \pm 1.4 \) fs [19], we obtain \( g_{\mu}/g_e = 1.0025 \pm 0.0060 \). The OPAL tau lifetime and \( \tau^- \rightarrow e^- \bar{\nu}_e \nu_\tau \) branching ratio are plotted in Fig. 3. The band is the Standard Model prediction assuming lepton universality. The width of the band corresponds to the uncertainty in the tau mass.

The strong coupling constant can be extracted from \( R_\tau = B(\tau^- \rightarrow \text{hadrons}^- \nu_\tau)/B(\tau^- \rightarrow e^- \bar{\nu}_e \nu_\tau) \) using the leptonic branching ratios and the \( \tau \) lifetime. In an earlier OPAL publication, \( R_\tau = 3.654 \pm 0.038 \) was determined using the leptonic branching ratio.
Fig. 3. The electronic branching ratio of the tau is plotted against the OPAL tau lifetime. The band is the prediction assuming $\mu - \tau$ universality and its width reflects the uncertainty associated with the tau mass.

based on 1990–1992 data [8] and the lifetime based on 1990–1993 data [19]. We follow the same prescription that was described in detail in Ref. [8]. Our new measurement of $B(\tau^{-} \to e^{-}\bar{\nu}_e\nu_{\tau})$, together with the $\tau$ lifetime and $\tau^{-} \to \mu^{-}\bar{\nu}_\mu\nu_{\tau}$ branching ratio, gives $R_{\tau} = 3.659 \pm 0.030$. The resulting $\alpha_{s}$ value is $0.377^{+0.015}_{-0.014-0.018}$ at $Q^2 = M_{\tau}^2$ and $0.1231 \pm 0.0013 \pm 0.0005$ at $Q^2 = M_{Z}^2$ where the first error is experimental and the second error is theoretical. Note, however, there may be an additional uncertainty of as much as $\pm 0.002$ [20] or $\pm 0.005$ [21] from effects beyond the SVZ parameterization [22] used to determine the coupling constant.

In summary, the branching ratio of the $\tau^{-} \to e^{-}\bar{\nu}_e\nu_{\tau}$ decay was measured using the 1991–1994 data samples recorded using the OPAL detector to be

$$R(\tau^{-} \to e^{-}\bar{\nu}_e\nu_{\tau}) = (17.78 \pm 0.10 \pm 0.09)\%$$

This new branching ratio supersedes the previous OPAL measurement and is consistent with the results of other experiments. The branching ratio has been used together with other measurements to test $e - \mu$ and $\mu - \tau$ lepton universality. The results indicate that the hypotheses of lepton universality in the charged current weak interaction are valid to within the 1% level.

Acknowledgements

It is a pleasure to thank the SL Division for the efficient operation of the LEP accelerator, the precise information on the absolute energy, and their continuing close cooperation with our experimental group. In addition to the support staff at our own institutions we are pleased to acknowledge the Department of Energy, USA, National Science Foundation, USA, Particle Physics and Astronomy Research Council, UK, Natural Sciences and Engineering Research Council, Canada, Fusoefeld Foundation, Israel Ministry of Science, Israel Science Foundation, administered by the Israel Academy of Science and Humanities, Minerva Gesellschaft, Japanese Ministry of Education, Science and Culture (the Monbusho) and a grant under the Monbusho International Science Research Program, German Israeli Bi-national Science Foundation (GIF), Direction des Sciences de la Matière du Commissariat à l'Energie Atomique, France, Bundesministerium für Forschung und Technologie, Germany, National Research Council of Canada, A.P.
