We measure the inclusive single muon charge asymmetry and the like-sign dimuon charge asymmetry in $p\bar{p}$ collisions using the full data set of $10.4\text{ fb}^{-1}$ collected with the D0 detector at the Fermilab Tevatron. The standard model predictions of the charge asymmetries induced by CP violation are small in magnitude compared to the current experimental precision, so non-zero measurements could indicate new sources of CP violation. The measurements differ from the standard model predictions of CP violation in these asymmetries with a significance of 3.6 standard deviations. These results are interpreted in a framework of $B$ meson mixing within the CKM formalism to measure the relative width difference $\Delta\Gamma_{B_\ell}/\Gamma_{B_\ell}$ between the mass eigenstates of the $B^0$ meson system, and the semileptonic charge asymmetries $a^{\ell}_q$ and $a_q^0$ of $B^0$ and $B^0_d$ mesons respectively.

I. INTRODUCTION

The D0 collaboration has published three measurements of the like-sign dimuon charge asymmetry in $p\bar{p}$ collisions at a center-of-mass energy of $\sqrt{s} = 1.96\text{ TeV}$ at the Fermilab Tevatron [1–3]. All these measurements have consistent results. The asymmetry obtained with 9 fb$^{-1}$ of integrated luminosity [3] deviates from the standard model (SM) prediction by 3.9 standard deviations, assuming that the only source of charge asymmetry is CP violation in meson-antimeson mixing of neutral $B$ mesons.

In this article we present the final measurement of the like-sign dimuon charge asymmetry using the full data set with an integrated luminosity of $10.4\text{ fb}^{-1}$ collected from 2002 until the end of Tevatron Run II in 2011. We use $6 \times 10^6$ like-sign dimuon events in our analysis. We obtain the raw like-sign dimuon charge asymmetry $A \equiv (N_{++} - N_{--})/(N_{++} + N_{--})$ by counting the numbers $N_{++}$ and $N_{--}$ of events with two positive or two negative muons, respectively. We identify several background processes producing the detector-related charge asymmetry $A_{\text{bkg}}$. We obtain the residual like-sign dimuon charge asymmetry $A_{\text{CP}}$, which is the asymmetry from CP-violating processes, by subtracting the asymmetry $A_{\text{bkg}}$ from the raw asymmetry $A$.

We also collect events with at least one muon. The number of events in this sample is $2 \times 10^9$. We obtain the raw inclusive single muon charge asymmetry $a \equiv (n^+ - n^-)/(n^+ + n^-)$ by counting the numbers $n^+$ and $n^-$ of positive and negative muons, respectively. We measure the detector-related charge asymmetry $a_{\text{bkg}}$ contributing to the raw asymmetry $a$. The residual inclusive single muon charge asymmetry $a_{\text{CP}}$ is obtained by subtracting the background asymmetry $a_{\text{bkg}}$ from $a$. The asymmetry $a_{\text{CP}}$ is found to be consistent with zero, and provides an important closure test for the method to measure the background asymmetries $a_{\text{bkg}}$ and $A_{\text{bkg}}$.

The dominant contribution to the inclusive single muon and like-sign dimuon background asymmetries $a_{\text{bkg}}$ and $A_{\text{bkg}}$ comes from the charge asymmetry of the muons produced in the decay in flight of charged kaons $K^- \to \mu^-\nu$ [4] or kaons that punch-through the absorber material of the D0 detector into the outer muon system. The interaction cross-sections of positive and negative kaons with the detector material are different [5], resulting in positive kaons having a longer inelastic interaction length than negative kaons. Positive kaons hence have a higher probability to decay, or to punch-through and produce a muon signal before they are absorbed in the detector material. Therefore, a critical measurement in this analysis, the fraction of muons from kaon decay or punch-through, is measured in data.

The detector-related systematic uncertainties of $a_{\text{bkg}}$ and $A_{\text{bkg}}$ are significantly reduced in our measurement...
by a special feature of the D0 experiment – the reversal of magnets polarities. The polarities of the toroidal and solenoidal magnetic fields were reversed on average every two weeks so that the four solenoid-toroid polarity combinations were exposed to approximately the same integrated luminosity. This allows for a cancellation of first-order effects related to the instrumental charge asymmetries [1].

The main expected source of like-sign dimuon events in $p\bar{p}$ collisions are $b\bar{b}$ pairs. One $b$ quark decays semileptonically to a “right-sign” muon, i.e., to a muon of the same charge sign as the parent $b$ quark. The other $b$ quark can produce a “wrong-sign” muon with its charge opposite to the charge of the parent $b$ quark. The origin of this “wrong-sign” muon is either due to $B^0$-$\bar{B}^0$ or $B^0_s$-$\bar{B}^0_s$ oscillation, or the sequential decay $b \rightarrow c \rightarrow \mu^+$. These processes produce CP violation in both mixing [6] and in the interference of $B^0$ and $B^0_s$ decay amplitudes with and without mixing [7]. CP violation in interference was not considered in [1–3], while it is taken into account in this paper.

An example of a process in which CP violation in mixing can occur is [8]

$$p\bar{p} \rightarrow b\bar{b}X,$$

$$b \rightarrow b \text{ hadron} \rightarrow \mu^- (“right-sign” \mu),$$

$$\bar{b} \rightarrow B^0_s \rightarrow B^0_s \rightarrow \mu^- (“wrong-sign” \mu);$$

and its CP-conjugate decay resulting in $\mu^+\mu^+$, where the probability of $B^0_s \rightarrow B^0_s$ is not equal to the probability of $\bar{B}^0_s \rightarrow B^0_s$.

An example of a process in which CP violation in interference can occur is [7]

$$p\bar{p} \rightarrow b\bar{b}X,$$

$$b \rightarrow b \text{ hadron} \rightarrow \mu^- (“right-sign” \mu),$$

$$\bar{b} \rightarrow B^0 \rightarrow B^0 \rightarrow D^+D^-,$$

$$D^- \rightarrow \mu^- (“wrong-sign” \mu);$$

and its CP-conjugate decay resulting in $\mu^+\mu^+$, where the probability of $B^0(\rightarrow \bar{B}^0) \rightarrow D^+D^-$ is not equal to the probability of $\bar{B}^0 \rightarrow B^0 \rightarrow D^+D^-$. The SM prediction of the like-sign dimuon charge asymmetry, and its uncertainty, are small in magnitude compared to the current experimental precision [7, 9]. This simplifies the search for new sources of CP violation beyond the SM which could contribute to the like-sign dimuon charge asymmetry. Currently, the only established source of CP violation is the complex phase of the Cabibbo-Kobayashi-Maskawa (CKM) matrix [10]. Although the CKM mechanism is extremely successful in describing all known CP violating processes studied in particle physics [11], it is insufficient to explain the dominance of matter in the universe [12].

Many features of the present measurement remain the same as in our previous publications, so that all details not described explicitly in this paper can be found in Refs. [2, 3]. The main differences of the present analysis with respect to [3] are:

- The muon quality selections are the same as in [3] except for the requirement of the number of track measurements in the silicon microvertex tracker (SMT). This change is discussed in Section III.

- The main emphasis of the present measurement is on the dependence of the charge asymmetry on the momentum of the muons transverse to the beam, $p_T$, on the muon pseudorapidity, $\eta$ [13], and on the muon impact parameter in the transverse plane, $IP$ [14]. The reason is to identify the detector-related effects that contribute to the observed asymmetry, and to help understand the origin of the asymmetry.

- In Refs. [2, 3] we measured the $K \rightarrow \mu$ fraction [15] by reconstructing the decays $K^{0}\rightarrow K^{+}\pi^{-}\nu$, $K^{+}\rightarrow K_{S}\pi^{+}\pi^{-}$, and $K_{S}\rightarrow \pi^{+}\pi^{-}$. This method requires a correction for muons with large IP that is described in Section V A. We have now also developed an independent method to obtain the background fractions using local measurements of the muon momentum by the muon identification system. This method, described in Section VB, is inherently insensitive to the muon IP. The comparison between these two methods provides an important validation of our measurement technique and estimate of the systematic uncertainties.

- We present the results in terms of model independent residual asymmetries $a_{CP}$ and $A_{CP}$ and the deviation of these asymmetries from the SM prediction. Assuming that the only sources of the like-sign dimuon charge asymmetry are CP violation in mixing and interference of neutral $B$ mesons, we measure the quantities determining these two types of CP violation: the semileptonic charge asymmetries $a_{CP}$ and $a_{CP}$ of $B^0$ and $B^0_s$ mesons, respectively, and the relative width difference $\Delta \Gamma_{d}/\Gamma_{d}$ of the $B^0$ system. These quantities are defined in Section VIII. Because our measurements are inclusive, other as yet unknown sources of CP violation could contribute to the asymmetries $a_{CP}$ and $A_{CP}$ as well. Therefore, the model-independent asymmetries $a_{CP}$ and $A_{CP}$ constitute the main result of our analysis. They are presented in a form which can be used as an input for alternative interpretations.

The outline of this article is as follows: the method and notations are presented in Section II; the details of data selection are given in Section III; the Monte Carlo (MC) simulation used in this analysis is discussed in Section IV.

TABLE III: Bins of (p_T, |η|). Global kinematic requirements are 1.5 < p_T < 25 GeV, (p_T > 4.2 GeV or |p_T| > 5.4 GeV), and |η| < 2.2.

| (p_T, |η|) bin | |η|     | p_T (GeV) |
|---------|--------|--------|-----------|
| 1       | < 0.7  | < 5.6  |
| 2       | < 0.7  | 5.6 to 7.0 |
| 3       | < 0.7  | > 7.0  |
| 4       | 0.7 to 1.2 | < 5.6 |
| 5       | 0.7 to 1.2 | > 5.6 |
| 6       | > 1.2  | < 3.5  |
| 7       | > 1.2  | 3.5 to 4.2 |
| 8       | > 1.2  | 4.2 to 5.6 |
| 9       | > 1.2  | > 5.6  |

The parameters obtained from data are presented in Sections V and VI. The measurement of residual charge asymmetries, after subtracting all background contributions, is presented in Section VII, the SM contributions to these asymmetries are discussed in Section VIII, and the interpretation of this measurement in terms of CP violation in mixing and interference of neutral B mesons is discussed in Section IX. Finally, the conclusions are collected in Section X. Appendix A presents the details of the fitting procedure used in this analysis.

II. METHOD

The expressions used in this analysis are described in detail in Ref. [2]. Here we emphasize the changes to our previous procedure. We use two sets of data:

i the inclusive muon data, collected with inclusive muon triggers, which include all events with at least one muon candidate passing quality and kinematic requirements described below;

ii the like-sign dimuon data, collected with dimuon triggers, which include all events with two muon can-

didates passing the same quality and kinematic requirements and the additional dimuon requirements described in Section III.

We select muons with 1.5 < p_T < 25 GeV and |η| < 2.2. In addition, we require either p_T > 4.2 GeV or |p_T| > 5.4 GeV, where p_T is the momentum of the muon in the proton beam direction. This selection is applied to ensure that the muon candidate is able to penetrate all three layers of the central or forward muon detector [3]. The upper limit on p_T is applied to suppress the contribution of muons from W and Z boson decays. Other muon requirements are discussed in Section III.

To study the IP, p_T, and |η| dependence of the charge asymmetry, we define three non-overlapping samples of inclusive muons according to the IP value, or six non-overlapping samples of like-sign dimuons according to the (IP₁,IP₂) values of the two muons. Here, IP₁ and IP₂ are the smaller and larger IP of the two muons, respectively. The definitions of these samples are given in Tables I and II. Figure 1 shows the IP distributions of one muon in the like-sign dimuon sample when the other muon has IP in the IP=1 (full line), IP=2 (dashed line), and IP=3 (dotted line) range. The distributions are normalized to have the same number of entries in the first bin [0, 10 μm] (only a fraction of this bin is shown in the figure). The vertical dashed lines show the definition of boundaries of the IP samples.
The background contributions come from muons produced in kaon and pion decay, or from hadrons that punch through the calorimeter and iron toroidal magnets to reach the outer muon detector. Another contribution is related to muon detection and identification. All these contributions are measured with data, with minimal input from simulation. Accordingly, the background asymmetry \( a_{bkg}^i \) can be expressed \([2]\) as

\[
a_{bkg}^i = a_\mu^i + f_K^i a_K^i + f_\pi^i a_\pi^i + f_p^i a_p^i.
\]

Here, the quantity \( a_\mu^i \) is the muon detection and identification asymmetry described later in this section. The fractions of muons from kaons, pions and protons reconstructed by the central tracker \([18]\) in a given \((p_T, |\eta|)\) bin \(i\) and misidentified as muons are \(f_K^i\), \(f_\pi^i\) and \(f_p^i\). Their charge asymmetries are \(a_K^i\), \(a_\pi^i\) and \(a_p^i\), respectively. We refer to these muons as “long” or “L” muons, since they are produced by particles traveling long distances before decaying within the detector. The tracks of \(L\) muons in the central tracker are generally produced by the parent hadron that subsequently decays at a large radius. The charge asymmetry of these muons results from the difference in the interactions of positively and negatively charged particles with the detector material, and is not related to CP violation. For charged kaons this difference arises from additional hyperon production channels in \(K^-\)nucleon reactions, which are absent for their \(K^+\)nucleon analogs. Since the interaction probability of \(K^+\) mesons is smaller, they travel further than \(K^-\) in the detector material, and have a greater chance of decaying to muons, and a larger probability to punch-through the absorber material thereby mimicking a muon signal. As a result, the asymmetry \(a_K\) is positive.

The muon detection and identification asymmetry \(a_\mu^i\) can be expressed as

\[
a_\mu^i \equiv (1 - f_{bkg}^i) \delta_i. \tag{6}
\]

The background fraction \(f_{bkg}^i\) is defined as \(f_{bkg}^i = f_K^i + f_\pi^i + f_p^i\). The quantity \(\delta_i\) is the charge asymmetry of single muon detection and identification. Due to the measurement method, this asymmetry does not include the possible track reconstruction asymmetry. A separate study presented in Ref. \([2]\) shows that track reconstruction asymmetry is consistent with zero within the experimental uncertainties, due to the regular reversal of the magnet polarities as discussed in Section III.

The background charge asymmetries \(a_K^i\), \(a_\pi^i\) and \(a_p^i\) are measured in the inclusive muon data, and include the detection and identification asymmetry. The parameters \(\delta_i\) are therefore multiplied by the factor \(1 - f_{bkg}^i\).

The residual asymmetry \(a_{CP}^i\) is obtained from Eq. \((4)\) by subtracting the background asymmetry \(a_{bkg}^i\) from the raw asymmetry \(a^i\). To interpret it in terms of CP violation in mixing, the asymmetry \(a_{CP}^i\) is expressed as

\[
a_{CP}^i = f_S a_S. \tag{7}
\]
Here the quantity $f^i_{\phi}$ is the fraction of muons from weak decays of $b$ and $c$ quarks and $\tau$ leptons, and from decays of short-lived mesons ($\phi, \omega, \eta, \rho, J/\psi, \psi'$, etc.) and Drell Yan in a given $(p_T, |\eta|)$ bin $i$. We refer to these muons as “short” or “$S$” muons, since they arise from the decay of particles within the beam pipe at small distances from the $p\bar{p}$ interaction point. The quantity $f^i_{\mu}$ is the charge asymmetry associated with these $S$ muons.

Since $S$ muons originate from inside the beam pipe, their production is not affected by interactions in the detector material, and once residual tracking, muon detection, and identification charge imbalances are removed, the muon charge asymmetry $a_S$ must therefore be produced only through CP violation in the underlying physical processes. Its dependence on the CP violation in mixing is discussed in Section VIII.

By definition the fractions $f^i_{K}$ and $f^i_{\pi}$ in Eq. (5) include only those background muons with the reconstructed track parameters corresponding to the track parameters of the kaon or pion, respectively. Such muons are mainly produced by $K^\pm$ and $\pi^\pm$ mesons that decay after passing through the tracking detector or punch-through the absorber material. The method used to measure the fractions $f^i_{K}$ and $f^i_{\pi}$ is described in Section V for details. In addition, there are background muons with reconstructed track parameters corresponding to the track parameters of the muon from the $K^\pm \rightarrow \mu^\pm \nu$ and $\pi^\pm \rightarrow \mu^\pm \nu$ decay. Such muons are mainly produced by the kaon and pion decays in the beam pipe and in the volume of the tracking detector. Technically, the muons produced in such decays should be treated as $S$ muons, since the parent hadron does not travel a long distance in the detector material and, therefore, these muons do not contribute to the background asymmetries. However, direct CP violation in semileptonic kaon or pion decay is significantly smaller than the experimental sensitivity [19] and is assumed to be zero. Therefore, such muons do not contribute to the asymmetry $a_S$.

To take into account the contribution of these $S$ muons from kaon and pion decay, we introduce the coefficients $C_K$ and $C_\pi$ [2, 3]. They are defined as

$$C_K = \frac{\sum^g_{i=1} f^i_K}{\sum^g_{i=1} (f^i_K + f^i_{\pi} + f^i_{\phi} + f^i_{\rho})}, \quad C_\pi = \frac{\sum^g_{i=1} f^i_{\pi}}{\sum^g_{i=1} (f^i_K + f^i_{\pi} + f^i_{\phi} + f^i_{\rho})}. \quad (8)$$

Here, $f^i_{\phi}$ and $f^i_{\rho}$ are the fractions of background muons with reconstructed track parameters corresponding to the track parameters of the muon from the $K^\pm \rightarrow \mu^\pm \nu$ and $\pi^\pm \rightarrow \mu^\pm \nu$ decay, respectively. The coefficients $C_K$ and $C_\pi$ reduce the fractions $f^i_{\pi}$ [20] because, by definition

$$f^i_{\pi} = \frac{f^i_{K}}{C_K} + \frac{f^i_{\pi}}{C_\pi} + \frac{f^i_{\phi}}{C_\phi} + \frac{f^i_{\rho}}{C_\rho} = 1. \quad (9)$$

In this expression we assume that the coefficients $C_K$ and $C_\pi$ are the same for each $(p_T, |\eta|)$ bin $i$. The variation of $C_K$ and $C_\pi$ in different $(p_T, |\eta|)$ bins produces a negligible impact on our result. The coefficients $C_K$ and $C_\pi$ are determined in simulation, which is discussed in Section IV. They are typically in the range 85% – 99%, except at large IP, see Table XV.

The total inclusive single muon charge asymmetry $a$, in a given IP sample, is given by the average of the nine individual measurements $a_i$ in $(p_T, |\eta|)$ bins $i$, weighted by the fraction $f^i_{\mu}$ of muons in each bin $i$:

$$a = \sum^9_{i=1} f^i_{\mu} a^i = a_{CP} + a_{bkg}, \quad (10)$$

where

$$a_{CP} \equiv \sum^9_{i=1} f^i_{\mu} a^i_{CP} = \sum^9_{i=1} f^i_{\mu} f^i_{S} a_S = f_S a_S, \quad (11)$$

$$a_{bkg} = \sum^9_{i=1} f^i_{\mu} a^i_{bkg}. \quad (12)$$

The quantities $f_S$ and $f^i_{\mu}$ are defined as

$$f_S \equiv \sum^9_{i=1} f^i_{\mu}, \quad (13)$$

$$f^i_{\mu} \equiv \frac{n^+_i + n^-_i}{\sum^9_{j=1} (n^+_j + n^-_j)}, \quad (14)$$

$$\sum^9_{i=1} f^i_{\mu} = 1. \quad (15)$$

B. Like-sign dimuon charge asymmetry

We now consider like-sign dimuon events in a given $(IP_1, IP_2)$ sample. All of the following equations are given for a particular $(IP_1, IP_2)$ sample. However, to simplify the presentation, we drop the index $(IP_1, IP_2)$ from all of them. The main principles of the measurement, namely applying the background corrections to the measured raw asymmetry to obtain the underlying CP asymmetry, are the same as for the inclusive single muon asymmetry. However, the dimuon measurement is more complex because the two muons can arise from different sources, and be in different $(p_T, |\eta|)$ and IP bins.

Consider first the case when $IP_1 = IP_2$. The number of events with two positive or two negative muons, when one muon is in the $(p_T, |\eta|)$ bin $i$ and another is in bin $j$, is $N_{ij}^{++}$ and $N_{ij}^{--}$, respectively. The like-sign dimuon asymmetry is defined as

$$A_{ij} = \frac{N_{ij}^{++} - N_{ij}^{--}}{N_{ij}^{++} + N_{ij}^{--}}. \quad (16)$$

The number of events $N_{ij}^{\pm\pm}$ can be expressed as

$$N_{ij}^{\pm\pm} = N_{ij}(1 \pm A_{ij}^{a})(1 \pm a^i_{bkg})(1 \pm a^j_{bkg}). \quad (17)$$
The total number of events in a given $(\mathrm{IP}_1, \mathrm{IP}_2)$ sample is $N_{ij}^{++} + N_{ij}^{--} = 2N_{ij}$ when higher-order terms in asymmetries are neglected. By definition $N_{ij} = N_{ji}$. The quantity $A_{\text{CP}}^{ij}$ is the residual charge asymmetry produced by $S$ muons.

The muon background asymmetry in a given $(p_T, |\eta|)$ bin in the dimuon events is

$$a_{\text{bkg}}^i = \frac{1}{2}A_{\mu}^i + \frac{1}{2}F_{\pi}^i a_{\pi}^i + \frac{1}{2}F_p^i a_p^i. \quad (18)$$

$$A_{\mu}^i = (2 - F_{\text{bkg}}^i) \delta_i. \quad (19)$$

Here, $\frac{1}{2}F_{\pi}^i$ and $\frac{1}{2}F_p^i$ are the fractions of muons produced by kaons, pions and protons reconstructed by the central tracker in a given $(p_T, |\eta|)$ bin $i$ but identified as muons. Following the definitions in Refs. [2, 3], for like-sign dimuon events the background fractions $F_{\pi}^i$ and $F_p^i$ are normalized per event (not per muon); this is the reason for the factors $1/2$ in Eq. (18). The quantity $F_{\text{bkg}}^i$ is defined as $F_{\text{bkg}}^i = F_{K}^i + F_{\pi}^i + F_p^i$. The asymmetries $a_{\pi}^i$, $a_p^i$, and $\delta_i$ are the same as in the inclusive muon sample.

The number of positive and negative muons from the like-sign dimuon events in the $(p_T, |\eta|)$ bin $i$ is

$$N_i^{\pm} = N_i^{++} + 9N_i^{\pm}. \quad (20)$$

The charge asymmetry $A^i$ of muons in the $(p_T, |\eta|)$ bin $i$, to first order in the asymmetries is

$$A^i = \frac{N_i^{+} - N_i^{-}}{N_i^{++} + N_i^{--}} = A_{\text{CP}}^i + A_{\text{bkg}}^i, \quad (21)$$

$$A_{\text{CP}}^i = \frac{N_i A_{\text{CP}}^{ij} + \sum_j N_{ij} A_{\text{CP}}^{ij}}{N_i + \sum_j N_{ij}}, \quad (22)$$

$$A_{\text{bkg}}^i = \frac{2N_i a_{\text{bkg}}^i + \sum_j N_{ij} (a_{\text{bkg}}^i + a_{\text{bkg}}^j)}{N_i + \sum_j N_{ij}}. \quad (23)$$

To interpret the asymmetry $A_{\text{CP}}^{ij}$ in terms of CP violation, it is expressed as

$$A_{\text{CP}}^{ij} = F_{SS}^{ij} A_S + F_{SL}^{ij} a_S. \quad (24)$$

The quantity $A_S$ is the charge asymmetry in the events with two like-sign $S$ muons. Its dependence on the parameters describing CP violation in mixing and CP violation in interference is discussed in Section VIII. The quantity $a_S$ is defined in Eq. (7). The quantity $F_{SS}^{ij}$ is the fraction of like-sign dimuon events with two $S$ muons, and $F_{SL}^{ij}$ is the fraction of like-sign dimuon events with one $S$ and one $L$ muon in given $(p_T, |\eta|)$ bins $i$ and $j$. Equation (24) reflects the fact that the events with two $S$ muons produce the charge asymmetry $A_S$; the events with one $S$ and one $L$ muon produce the charge asymmetry $a_S$, while the events with both $L$ muons do not produce a CP-related charge asymmetry.

Multiplying Eq. (21) by the fraction $F_\mu^i$ of muons in a given $(p_T, |\eta|)$ bin $i$, and summing over $i$, we reproduce the expression of the like-sign dimuon charge asymmetry in Refs. [2, 3]:

$$A = \sum_{i=1}^{9} F_\mu^i A^i = A_{\text{CP}} + A_{\text{bkg}}, \quad (25)$$

$$A_{\text{CP}} = \sum_{i=1}^{9} F_\mu^i A_{\text{CP}}^i = F_{SS} A_S + F_{SL} a_S, \quad (26)$$

$$A_{\text{bkg}} = \sum_{i=1}^{9} F_\mu^i \{ A_{\mu}^i + F_K a_K^i + F_\pi a_\pi^i + F_p a_p^i \}. \quad (27)$$

Here the fraction $F_\mu^i$ is defined as

$$F_\mu^i = \frac{N_i^{+} + N_i^{-}}{\sum_{j=1}^{9} (N_j^{+} + N_j^{-})}, \quad \sum_{i=1}^{9} F_\mu^i = 1. \quad (28)$$

From Eqs. (22), (24), (26), and (28) it follows that

$$F_{SS} = \sum_{i=1}^{9} \left( N_i A_{\text{CP}}^{ij} + \sum_{j=1}^{9} N_{ij} F_{SS}^{ij} \right) \frac{N_i}{N_{\text{tot}}}, \quad (29)$$

$$F_{SL} = \sum_{i=1}^{9} \left( N_i A_{\text{CP}}^{ij} + \sum_{j=1}^{9} N_{ij} F_{SL}^{ij} \right) \frac{N_i}{N_{\text{tot}}}, \quad (30)$$

$$N_{\text{tot}} = \sum_{i=1}^{9} N_i = \sum_{i=1}^{9} \left( N_i + \sum_{j=1}^{9} N_{ij} \right). \quad (31)$$

Here $N_{\text{tot}}$ is the total number of dimuon events in a given IP$_1$IP$_2$ sample. The quantity $F_{LL}$ gives the fraction of the like-sign dimuon events with two $L$ muons.

$$F_{SS} + F_{SL} + F_{LL} = 1, \quad (32)$$

$$2F_{LL} + F_{SL} = \sum_{i=1}^{9} \left( \frac{F_K^i}{C_K} + \frac{F_\pi^i}{C_\pi} + \frac{F_p^i}{C_p} \right). \quad (33)$$

We solve for the fractions $F_{SS}$, $F_{SL}$ and $F_{LL}$ using Eqs. (32), (33) and the ratio

$$R_{LL} = \frac{F_{LL}}{F_{SL} + F_{LL}}, \quad (34)$$

which is obtained from the simulation. The simulation used in this analysis is discussed in Section IV.

For the sample of dimuon events with IP$_1$ $\neq$ IP$_2$, it can be shown that the expressions (21) – (27) remain the same with background fractions defined as

$$F_K^i(\text{IP}_1, \text{IP}_2) = \frac{1}{2} \left[ F_K^i(\text{IP}_1) + F_K^i(\text{IP}_2) \right], \quad (35)$$

$$F_\pi^i(\text{IP}_1, \text{IP}_2) = \frac{1}{2} \left[ F_\pi^i(\text{IP}_1) + F_\pi^i(\text{IP}_2) \right], \quad (36)$$

$$F_p^i(\text{IP}_1, \text{IP}_2) = \frac{1}{2} \left[ F_p^i(\text{IP}_1) + F_p^i(\text{IP}_2) \right]. \quad (37)$$

Here, $F_K^i(\text{IP}_1)$ is the number of $K \to \mu$ muons with the impact parameter in the IP$_1$ range normalized to
the total number of events in the (IP$_i$,IP$_j$) sample. The fractions $F^i_1$, $F^i_2$, $F^i_3$ and $F^i_4$ are defined similarly for $\pi \rightarrow \mu$ and $p \rightarrow \mu$ muons.

Hence, in order to extract the CP-violating asymmetries $a_{CP}$ and $A_{CP}$ from the binned raw asymmetries $a^i$ and $A^i$, the following quantities are required:

- The fractions $f^i_{K}$, $f^i_{\pi}$, $f^i_{p}$, $f^i_{\mu}$, $F^i_{K}$, $F^i_{\pi}$, $F^i_{p}$ and $F^i_{\mu}$, in bins $i$ of $(p_T, |\eta|)$, each IP sample (Tables V and VI).
- The background asymmetries $a^i_{K}$, $a^i_{\pi}$, $a^i_{p}$ and $\delta_i$, in bins $i$ of $(p_T, |\eta|)$. They do not depend on the IP sample, see Section VI for details.

All these quantities are extracted directly from data with minimal contribution from the MC simulation.

The remainder of this article describes the extraction of these parameters, and the subsequent interpretation of the asymmetries $A_{CP}$ and $a_{CP}$.

### III. MUON SELECTION

The D0 detector is described in Refs. [17, 21–23]. It consists of a magnetic central-tracking system that comprises a silicon microstrip tracker (SMT) and a central fiber tracker (CFT), both located within a 2 T superconducting solenoidal magnet [21]. The muon system [17, 22] is located beyond the liquid argon-uranium calorimeters that surround the central tracking system, and consists of a layer A of tracking detectors and scintillation trigger counters before 1.8 T iron toroids, followed by two similar layers B and C after the toroids. Tracking for $|\eta| < 1$ relies on 10-cm wide drift tubes, while 1-cm minidrift tubes are used for $1 < |\eta| < 2$.

The polarities of the toroidal and solenoidal magnetic fields were reversed on average every two weeks so that the four solenoid-toroid polarity combinations were exposed to approximately the same integrated luminosity. This allows for a cancellation of first-order effects related to the instrumental asymmetries [1]. To ensure more complete cancellation, the events are weighted according to the number of hits for each data sample corresponding to a different configuration of the magnet polarities. These weights are given in Table IV. The weights for inclusive muon and the like-sign dimuon samples are different due to different trigger requirements. The effective reduction of statistics of the like-sign dimuon sample due to this weighting is less than 2%.

As discussed previously in Section II, the inclusive muon and like-sign dimuon samples are obtained from data collected with single and dimuon triggers, respectively. Charged particles with transverse momentum in the range $1.5 < p_T < 25$ GeV and with pseudorapidity $|\eta| < 2.2$ are considered as muon candidates. We also require either $p_T > 4.2$ GeV or a longitudinal momentum component $|p_z| > 5.4$ GeV. Muon candidates are selected by matching central tracks with a segment reconstructed in the muon system and by applying tight quality requirements aimed at reducing false matching and background from cosmic rays and beam halo [17]. The transverse IP of the charged track matched to the muon relative to the reconstructed $p\bar{p}$ interaction vertex must be smaller than 0.3 cm, with the longitudinal distance from the point of closest approach to this vertex smaller than 0.5 cm. We use track parameters of the track reconstructed in the CFT and SMT and do not use the muon momentum and azimuthal angle measurements provided by the muon system. Strict quality requirements are also applied to the tracks and to the reconstructed $p\bar{p}$ interaction vertex. The details of these requirements can be found in Ref. [2]. The inclusive muon sample contains all muons passing the selection requirements. If an event contains more than one muon, each muon is included in the inclusive muon sample.

The like-sign dimuon sample contains all events with at least two muon candidates with the same charge. These two muons are required to have the same associated $p\bar{p}$ interaction vertex, and an invariant mass larger than 2.8 GeV to minimize the number of events in which both muons originate from the same $b$ quark. The invariant mass of two muons in the opposite-sign and like-sign dimuon sample is shown in Fig. 3. If more than two muons pass the single muon selection, the classification into like-sign or opposite-sign is done using the two muons with the highest $p_T$. In the like-sign dimuon sample $\approx 0.7\%$ of the events have more than two muons.

In addition to these selections, which are identical to the selections of Refs. [2, 3], we apply a stronger requirement on the number of hits in the SMT included in the track associated with the muon. The SMT [23] has axial detector strips parallel to the beam, and stereo detector strips at an angle to the beam. We require that the muon track contains at least three axial SMT hits, instead of the requirement of two such hits in [3]. On average, a track passing through the SMT has hits in four layers of the SMT. The SMT measurements in axial strips determine the IP precision, and this stronger requirement substantially reduces the number of muons with incorrectly measured IP. The tracks with exactly two axial SMT hits include tracks with one of the two SMT hits incorrectly associated. For such tracks, the IP can be measured to be large. As a result, muons produced with small IP migrate to the sample with large IP, as can be

MC simulations are used in a limited way, as discussed in Section VIII. To produce the simulated events we use the PYTHIA v6.409 event generator [24], interfaced to the EVTGEN decay package [25], and CTEQ6L1 parton distribution functions [26]. The generated events are propagated through the D0 detector using a GEANT-based program [27] with full detector simulation. The response in the detector is digitized, and the effects of multiple interactions at high luminosity are modeled by overlaying hits from randomly selected $p\bar{p}$ collisions on the digitized hits from MC. The complete events are reconstructed with the same program as used for data, and, finally, analyzed using the same selection criteria described above for data.

In this analysis two types of MC sample are used:

- Inclusive $p\bar{p}$ collisions with minimum interaction transverse energy at the generator level $E_T^{\text{min}} = 20$ GeV.
- A simulation of $p\bar{p} \rightarrow b\bar{b}X$ and $p\bar{p} \rightarrow c\bar{c}X$ final states, with $E_T = 0$ GeV, producing two muons with an additional requirement that the produced muons have $p_T > 1.5$ GeV and $|\eta| < 2.2$.

The second sample is especially useful to extract quantities for the signal inclusive muon and dimuon events, because it is generated with almost no kinematic bias, as discussed in Section VIII.

V. MEASUREMENT OF BACKGROUND FRACTIONS

A. The $K^{*0}$ method

A kaon, pion, or proton can be misidentified as a muon and thus contribute to the inclusive muon and the like-sign dimuon samples. This can happen because of pion and kaon decays in flight, or punch-through. We do not distinguish these individual processes, but rather measure the total fraction of such particles using data. In the following, the notation “$K \rightarrow \mu^+$” stands for “kaon misidentified as a muon,” and the notations “$\pi \rightarrow \mu$” and “$p \rightarrow \mu$” have corresponding meanings for pions and protons.

The fraction $f_K$ is measured by reconstructing the decays $K^{*0} \rightarrow K^{+}\pi^-$ with $K \rightarrow \mu$, and $K^{*+} \rightarrow K_S^{0}\pi^+$ with one of the pions from $K_S \rightarrow \pi^+\pi^-$ decay misidentified as a muon. This method is described in detail in [2, 3]. The main features of this method are repeated here.

The relation between the fraction $f_{K^{*0}}$ of $K \rightarrow \mu$ originating from the decay $K^{*0} \rightarrow K^{+}\pi^-$ and the fraction $f_K$ in each $(p_T,|\eta|)$ bin $i$ is

$$f_{K^{*0}} = \varepsilon_0^i R'(K^{*0}) f_K.$$

Here $R'(K^{*0})$ is the fraction of all kaons that result from $K^{*0} \rightarrow K^{+}\pi^-$ decays, and $\varepsilon_0^i$ is the efficiency to reconstruct the charged pion from the $K^{*0} \rightarrow K^{+}\pi^-$ decay,
provided that the $K \rightarrow \mu$ track is reconstructed. The kinematic parameters of the charged kaon are required to be in the $(p_T, |\eta|)$ bin $i$.

We also select $K_S$ mesons and reconstruct $K^{*+} \rightarrow K_S\pi^+$ decays. One of the pions from the decay $K_S \rightarrow \pi^+\pi^-$ is required to be misidentified as a muon. This requirement ensures that the flavor composition of the samples containing $K \rightarrow \mu$ and $K_S \rightarrow \pi^+\pi^- \rightarrow \pi^+\mu^+$ is the same [3]. The number of $K^{*+} \rightarrow K_S\pi^+$ decays in each $(p_T, |\eta|)$ bin $i$ is

$$N^i(K^{*+} \rightarrow K_S\pi^+) = \epsilon^i_c N^i(K_S) R^i(K^{*+}),$$

(39)

where $R^i(K^{*+})$ is the fraction of $K_S$ mesons that result from $K^{*+} \rightarrow K_S\pi^+$ decays, and $\epsilon^i_c$ is the efficiency to reconstruct the charged pion in the $K^{*+} \rightarrow K_S\pi^+$ decay, provided that the $K_S$ meson is reconstructed. The kinematic parameters of the $K_S$ meson are required to be in the $(p_T, |\eta|)$ bin $i$. We use isospin invariance to set

$$R^i(K^{*0}) = R^i(K^{*+}).$$

(40)

This relation is also confirmed by data from LEP as discussed in Ref. [2]. We apply the same kinematic selection criteria to the charged kaon and $K_S$ candidates, and use exactly the same criteria to select an additional pion and reconstruct the $K^{*0} \rightarrow K^+\pi^-$ and $K^{*0} \rightarrow K_S^+\pi^+$ decays. We therefore assume that

$$\epsilon^i_0 = \epsilon^i_c.$$  

(41)

We assign the systematic uncertainty related to this assumption, see Section V C for details.

From Eqs. (38)–(41), we obtain

$$f^i_K = \frac{N^i(K_S)}{N^i(K^{*+} \rightarrow K_S\pi^+)} f^i_{K^{*0}}.$$  

(42)

This expression is used to measure the kaon fraction $f^i_K$ in the inclusive muon sample without dividing it into the IP samples. It is based on the equality (41) of the efficiencies to reconstruct the $K^{*0} \rightarrow K^+\pi^-$ and $K^{*+} \rightarrow K_S^+\pi^+$ decays, provided that the $K^+$ and $K_S$ candidates are reconstructed. This equality is verified in simulation for a full data sample [2]. However, in a given IP sample the efficiencies $\epsilon^i_0$ and $\epsilon^i_c$ become unequal because of the differences between the $K_S$ and $K^+$ tracks explained below.

If the $K^\pm \rightarrow \mu^\pm\nu_e$ decay occurs within the tracking volume, the track parameters of charged $K$ meson can be biased due to the kink in the $K \rightarrow \mu$ trajectory. Such biased $K \rightarrow \mu$ tracks tend to populate the sample with large IP. The bias in the $K$ meson track parameters propagates into a reduced efficiency of $K^{*0} \rightarrow K^+\pi^-$ reconstruction. This reduction can be seen in Fig. 5 where the ratio of the $K^{*0} \rightarrow K^+\pi^-$ reconstruction efficiencies $\epsilon(K^{*0}, IP)/\epsilon(K^{*0})$ in a given IP sample and in the total inclusive muon sample is shown. These ratios are obtained in simulation.

The $K_S$ meson is reconstructed from $\pi^+$ and $\pi^-$ tracks with one of the pions required to be misidentified as a muon. The quality of the $K_S \rightarrow \pi^+\pi^-$ vertex, and the condition that the $\pi^+\pi^-$ mass be consistent with the $K_S$ mass, are imposed to select the $K_S$ candidate. As a result, the sample of $K_S$ candidates with large IP does not contain an increased contribution from the biased $K_S$ track measurement. Therefore, the $K^{*+} \rightarrow K_S\pi^+$ reconstruction efficiency in the sample with large $K_S$ track IP can be different from the $K^{*0} \rightarrow K^+\pi^-$ reconstruction efficiency, and the estimate of $f^i_K(IP)$ in the large $K^+$ IP sample using Eq. (42) is biased.

To avoid this bias, the fractions $f^i_K(IP)$ in a given IP sample are measured using the following expression:

$$f^i_K(IP) = f^i_{K^{*0}} \frac{f^i_K(IP)}{f^i_{K^{*0}}} \frac{\epsilon^i(K^{*0})}{\epsilon^i(K^{*0}, IP)}.$$  

(43)

The fractions $f^i_{K^{*0}}(IP)$ and $f^i_{K^{*0}}$ are measured in the IP sample and in the total inclusive muon sample, respectively. The fraction $f^i_K$ is obtained using Eq. (42). The ratio of efficiencies $\epsilon^i(K^{*0}, IP)/\epsilon^i(K^{*0})$ is taken from simulation and is shown in Fig. 5. The mean value of $\epsilon^i(K^{*0}, IP)/\epsilon^i(K^{*0})$ is 1.01 ± 0.01 for the IP=1 sample, 0.90 ± 0.03 for the IP=2 sample and 0.79 ± 0.06 for the IP=3 sample. The uncertainties are due to limited MC statistics.

The procedure to measure the related background fractions $f_{L}^i$ and $f_{S}^i$ in the total inclusive muon sample are shown in Fig. 6. The background fractions in different IP samples are given in Table V. For reference, we also give in Table V the values $f_L/C_L$ and $f_S/C_S$ [20]. These values for all inclusive muon events can be compared directly with the corresponding background fraction (15.96 ± 0.24)% and (30.1 ± 1.6)% respectively in [3].

Approximately 17% (32%) of muons in the inclusive muon sample are determined to arise from kaon (pion) misidentification, with less than 1% due to proton punch through and fakes. The remaining ≈50% of the sample are muons from heavy-flavor decay.

The background fractions vary by a factor of more than five between the IP=1 and IP=3 samples. Such a large variation is expected. The parents of $L$ muons are dominantly produced in the primary interaction and decay outside the tracking volume. The $S$ muons are dominantly produced in decays of heavy quarks and their tracks have large IP. Therefore, the fraction of $L$ muons in the sample with small IP is substantially enhanced. They give the main contribution to the background asymmetry in this sample. On the contrary, the fraction of $L$ muons in the large IP sample is suppressed, and the kaon and detector asymmetries have approximately the same magnitude, see Table VIII for details. The comparison of our prediction and the observed raw asymmetry in different $(p_T, |\eta|)$ and IP bins therefore allows us to verify our background measurement method.

The procedure to measure the background fractions in the like-sign dimuon sample is described in [3] and is not
changed for this analysis. To obtain the quantity $F_K$ of $K \to \mu$ tracks in the like-sign dimuon sample we use the relation similar to Eq. (42):

$$F_K = \frac{N^i(K_S)}{N^i(K^{*+} \to K_S\pi^+)} F_{K^{*+}}.$$  

Here $F_{K^{*+}}$ is the fraction of $K^{*0} \to K^+\pi^-$ decays with $K \to \mu$ in the $(p_T,|\eta|)$ bin $i$ in the like-sign dimuon sample. The numbers $N^i(K_S)$ and $N^i(K^{*+} \to K_S\pi^+)$ are obtained from the inclusive muon sample. The kinematic parameters of the charged kaon and $K_S$ meson are required to be in the $(p_T,|\eta|)$ bin $i$.

In the samples with the $(IP_1,IP_2)$ selection the background fractions $F_K^i(IP_1)$ and $F_K^i(IP_2)$ are determined separately for the IP1 and IP2 kaon and the total background fractions are obtained using Eq. (35). The fractions $F_K^i(IP_1)$ and $F_K^i(IP_2)$ are obtained using the expression

$$F_K^i(IP_{1,2}) = F_K^i \frac{F_{K^{*+}}^i(IP_{1,2})}{F_{K^{*+}}^i} \frac{\varepsilon_i(K^{*+})}{\varepsilon_i(K^{*0},IP_{1,2})}. \quad (45)$$

The fractions $F_{K^{*+}}^i(IP_1)$ and $F_{K^{*+}}^i(IP_2)$ are measured using the IP1 and IP2 kaons, respectively. The fraction $F_K^i$ is obtained using Eq. (44).

The values of $F_K^i$, $F_p^i$ and $F_p^i$ in the total like-sign dimuon sample are shown in Fig. 7. The background fractions in different $(IP_1,IP_2)$ samples are given in Table VI. For reference, we also give the values $F_K/C_K$ and $F_p/C_p$ [20]. These values for all like-sign dimuon events can be compared directly with the corresponding background fractions (13.78 $\pm$ 0.38)% and (24.81 $\pm$ 1.34)% respectively, in Ref. [3]. Table VI also contains the values of $F_{SS}$ and $F_{SL}$ for each $(IP_1,IP_2)$ sample and for the total sample of like-sign dimuon events.

For the like-sign dimuon sample approximately 6.5% (12.5%) of muons arise from kaon (pion) misidentification, with less than 0.25% from proton punch through or fakes. These values are derived from Table VI taking into account that the background fractions given in this table are defined per dimuon event. We find that 69% of the events have both muons from heavy-flavor decays, and a further 23% have one muon from heavy-flavor decay. Similar to the inclusive muon events, the background fractions are considerably reduced and the signal contribution is increased in the samples with large muon IP.
TABLE VI: Background and signal fractions in the (IP$_1$,IP$_2$) samples of the like-sign dimuon sample. The column “All IP” corresponds to the full like-sign dimuon sample without dividing it into the (IP$_1$,IP$_2$) samples. Only statistical uncertainties are given.

FIG. 6: Fraction of (a) $K \rightarrow \mu$ tracks, (b) $\pi \rightarrow \mu$ tracks and (c) $p \rightarrow \mu$ tracks in the inclusive muon sample as a function of the kaon, pion and proton ($p_T, |\eta|$) bin $i$, respectively. Only statistical uncertainties are shown. The horizontal dashed lines show the mean values. The vertical dashed lines separate the ($p_T, |\eta|$) bins corresponding to the central, intermediate, and forward regions of the detector, respectively.

FIG. 7: Fraction of (a) $K \rightarrow \mu$ tracks, (b) $\pi \rightarrow \mu$ tracks and (c) $p \rightarrow \mu$ tracks per event in the like-sign dimuon sample as a function of the kaon, pion and proton ($p_T, |\eta|$) bin $i$, respectively. Only statistical uncertainties are shown. The horizontal dashed lines show the mean values. The vertical dashed lines separate the ($p_T, |\eta|$) bins corresponding to the central, intermediate, and forward regions of the D0 detector, respectively.
B. The local variables method

The $K^{*0}$ method presented in Section VA depends on the validity of Eqs. (40) and (41) and on the ratio $\varepsilon'(K^{*0}, \text{IP})/\varepsilon'(K^{*0})$, which cannot be verified directly in our data. To assign the systematic uncertainties due to these input we develop a complimentary method of local variables presented below. The systematic uncertainty on the background fractions is assigned following the comparison of two fully independent methods. It is discussed in Section VC.

The D0 muon detection system [22] is capable of measuring the local momentum of the identified muon. A distinctive feature of the muons included in the background fractions $f_K, f_\pi, F_K$ and $F_\pi$ is that their track parameters measured by the tracking system (referred to as “central” track parameters) correspond to the original kaon or pion, while the track parameters measured by the muon system (referred to as “local” track parameters) correspond to the muon produced in kaon or pion decay. Thus, these two measurements are intrinsically different. We exploit this feature in our event selection by selecting muons with $\chi^2 < 12$ for 4 d.o.f. [3], where $\chi^2$ is calculated from the difference between the track parameters measured in the central tracker and in the local muon system. In addition to this selection, in the present analysis we develop a method of measuring the background fractions using the difference in the central and local measurements of the muon track parameters.

We define a variable $X$ as

$$X = \frac{p(\text{local})}{p(\text{central})}. \quad (46)$$

Here $p(\text{local})$ and $p(\text{central})$ are the momenta measurements of the local and central tracks, respectively. Figure 8(a) shows the normalised distributions of this variable for $S$ muons and $L$ muons in the $(p_T, |\eta|)$ bin 2 of the inclusive muon sample. The distribution for $S$ muons is obtained using identified muons from the decay $D^0 \rightarrow K^- \mu^+ \nu$. The distribution for $L$ muons is obtained as a linear combination of the distributions of $K \rightarrow \mu$ tracks and $\pi \rightarrow \mu$ tracks with the coefficients corresponding to their fractions in the inclusive muon sample. These two distributions are shown separately in Fig. 8(b). The distribution for $K \rightarrow \mu$ tracks is obtained using kaons produced in the $\phi \rightarrow K^+K^-$ decay and misidentified as muons. The distribution for $\pi \rightarrow \mu$ tracks is obtained using pions produced in the $K_S \rightarrow \pi^+\pi^-$ decay and misidentified as muons. Since we select muons with at least 3 hits in SMT, the $K_S$ decay is forced to be within the beam pipe. All these distributions are obtained using exclusively the events in a given $(p_T, |\eta|)$ bin.

Figure 8(a) shows that the distribution for $L$ muons is shifted towards lower $X$ values reflecting the fact that a part of the total momentum of the kaon or pion is taken away by the neutrino. The difference between the distributions for $K \rightarrow \mu$ muons and $\pi \rightarrow \mu$ muons is relatively small. This observation corresponds to the expectation that the fraction of momentum in the laboratory frame taken away by the neutrino is similar in $K \rightarrow \mu$ and $\pi \rightarrow \mu$ decays. The position of the maximum of the distribution of the $X$ variable for $S$ muons is lower than 1 because of the muon energy loss in the detector material. The typical energy loss of muons in the material of D0 detector is $3-4$ GeV depending on muon $\eta$ [17].

Another variable used in this study is the difference between the polar angles of the local and central tracks

$$Y = |\theta(\text{local}) - \theta(\text{central})|. \quad (47)$$

Figure 9(a) shows the normalised distributions of this variable for $S$ muons and $L$ muons in the $(p_T, |\eta|)$ bin 2 of the inclusive muon sample. Figure 9(b) presents the separate distributions of $K \rightarrow \mu$ and $\pi \rightarrow \mu$ tracks. The distribution for $L$ muons is wider than that for $S$ muons. A part of the four-momentum of $L$ muons is taken away by an invisible neutrino. This missing momentum results in a kink in the $K \rightarrow \mu$ or $\pi \rightarrow \mu$ track, which produces a wider $Y$ distribution.

We fit the distribution of $X$ and $Y$ variables in each $(p_T, |\eta|)$ bin $i$ of each IP sample of the inclusive muon sample using the templates for $S$ muons and $L$ muons and determine the background fraction $f_{\text{bkg}}$ for this IP sample. Since the distributions for $K \rightarrow \mu$ tracks and $\pi \rightarrow \mu$ tracks are similar, this method is not sensitive to the separate fractions $f_K$ and $f_\pi$. Therefore, the ratio of these two fractions is fixed to the value measured in data using the $K^{*0}$ method. The templates for each $(p_T, |\eta|)$ bin $i$ are built using exclusively the events in a
given \((p_T, |\eta|)\) bin. The background fraction in a given IP sample is computed using the relation

\[
    f^{\text{bkg}}_\mu = \sum_{i=1}^{9} f^{i}_\mu f^{i}_\text{bkg},
\]

where the sum is taken over all \((p_T, |\eta|)\) bins. Figures 10 and 11 show an example of this fit for the \(X\) and \(Y\) variables, respectively, in the \((p_T, |\eta|)\) bin 2. Figures 10(a) and 11(a) show the normalised distributions of \(X\) and \(Y\) in the inclusive muon sample, and the expected distributions obtained from the fit. These distributions are indistinguishable on this scale, since the statistics in the inclusive muon sample is very large. Figures 10(b) and 11(b) show the difference between the observed and expected normalised distributions. The quality of the description of the observed distributions is very good. The fit of these differences to their average gives \(\chi^2/\text{d.o.f.} = 48/48\) for \(X\) and \(42/59\) for \(Y\).

The resulting background fractions in different IP samples are given in Table VII. Only the statistical uncertainties are given. The statistical uncertainty of the measurements with \(X\) and \(Y\) variables is less than the difference between them. Therefore, we take the weighted average of these two measurements as the central value of the background fraction \(f^{\text{bkg}}(\text{local})\) and assign half of the difference between them as its uncertainty.

The obtained values \(f^{\text{bkg}}(\text{local})\) can be compared with the background fractions \(f^{\text{bkg}}(K^{*0})\) measured using the \(K^{*0}\) method described in the previous section. These
TABLE VII: Comparison of background fractions measured using local variables with the background fractions obtained using $K^{*0}$ production. The relative difference $\delta_f$ between two independent measurements is also shown. This quantity is defined in Eq. (49). Only statistical uncertainties are shown.

fractions, as well as the relative difference

$$\delta_f \equiv \frac{f_{\text{bkg}}(\text{local}) - f_{\text{bkg}}(K^{*0})}{f_{\text{bkg}}(K^{*0})}$$  \hspace{1cm} (49)$$

are also given in Table VII.

All templates for the measurement of background fractions with local variables are obtained using the inclusive muon sample. It makes this measurement self-consistent. The available statistics of the dimuon events is insufficient to obtain the corresponding templates for the measurement in the dimuon sample. Therefore, the background fractions are measured only in the inclusive muon sample, and the method of local variables is used as a cross check of the corresponding quantities obtained with the $K^{*0}$ method.

The background measurements with these two methods are fully independent. They are based on different assumptions and are subject to different systematic uncertainties, which are not included in the uncertainty of $\delta_f$ shown in Table VII. The background fraction changes by more than six times between the samples with small and large IP. Nevertheless, the two methods give consistent results for all IP samples. The remaining difference between them, which exceeds two standard deviations only for the sample with small IP, is assigned as a systematic uncertainty, and is discussed in Section V C. Thus, the background measurement with local variables provides an independent and important confirmation of the validity of the analysis procedure used to determine the background fractions.

C. Systematic uncertainties on backgrounds

The systematic uncertainties for the background fractions are discussed in Refs. [2, 3]. Here we describe the changes applied in the present analysis. In our previous measurement the systematic uncertainty of the fraction $f_K$ was set to 9% [2, 3]. In the present analysis we perform an alternative measurement of background fractions using the local variables. The results of two independent measurements, given in Table VII, are statistically different only for the IP=1 sample. We attribute this difference to the systematic uncertainties of the two measurements. Since the background fractions $f_\pi$ and $f_p$ are derived using the measured fraction $f_K$ [2], we set the relative systematic uncertainty of $f_\pi$, $f_p$, and $f_\mu$ in each IP sample to $\delta_f/\sqrt{2}$, or to $\sigma(\delta_f)/\sqrt{2}$, whichever value is larger. Here, $\sigma(\delta_f)$ is the uncertainty of $\delta_f$. We assume the full correlation of this uncertainty between $f_K$, $f_\pi$, and $f_p$. Numerically, the value of the systematic uncertainty of $f_K$ is about 6.3% for the IP=1 sample and 4.5% for the IP=3 sample, which is smaller than, but consistent with, our previous assignment [3] of the systematic uncertainty on the $f_K$ fraction.

The procedure to determine the relative systematic uncertainty on the ratio $F_K/f_K$ is discussed in Ref. [3]. Following this procedure we set this uncertainty to 2.9%, compared to 3.0% uncertainty applied in [3] where the change is due to the addition of the final 1.4 fb$^{-1}$ of data.

Other systematic uncertainties remain as in [2, 3]. Namely, the systematic uncertainties on the ratios of multiplicities $n_\pi/n_K$ and $n_p/n_K$, required to compute $f_\pi$ and $f_p$, are set to 4%. The systematic uncertainties on the ratios of multiplicities $N_\pi/N_K$ and $N_p/N_K$, required to compute $F_\pi$ and $F_p$, are also set to 4%.

VI. MEASUREMENT OF BACKGROUND ASYMMETRIES

The background asymmetries arise from the difference of interaction cross-section of positive and negative particles with the detector material. The asymmetries for kaons, pions and protons are denoted as $a_K$, $a_\pi$ and $a_p$, respectively. The origin of different asymmetries and their measurement techniques are discussed in detail in Ref. [2, 3]. The asymmetry $a_K$ is measured by reconstructing exclusive decays $K^{*0} \rightarrow K^+\pi^-$ and $\phi \rightarrow K^+K^-$ with $K \rightarrow \mu$. The asymmetry $a_\pi$ is measured using the reconstructed $KS \rightarrow \pi^+\pi^-$ decay with $\pi \rightarrow \mu$. The asymmetry $a_p$ is measured by reconstructing the $\Lambda \rightarrow p\pi^-\pi^-$ decay with the proton misidentified as a muon. All these asymmetries are measured directly in data and therefore they include the possible asymmetry induced by the trigger.

Another source of background asymmetry is the difference between positive and negative muon detection, identification and track reconstruction. This asymmetry $\delta$ is measured by reconstructing decays $J/\psi \rightarrow \mu^+\mu^-$ using
track information only and then counting the tracks that have been identified as muons. Due to the measurement method, the asymmetry $\delta$ does not include the possible track reconstruction asymmetry. A separate study presented in Ref. [2] shows that track reconstruction asymmetry is consistent with zero within the experimental uncertainties. This is a direct consequence of the regular reversal of magnet polarities discussed in Section III.

In this analysis all background asymmetries are measured in $(p_T, |\eta|)$ bins. It was verified in Ref. [3] that the background asymmetries do not depend on the particle IP within the statistical uncertainties of their measurement. Therefore, the same values of background asymmetries are used for different IP samples. The background asymmetries obtained are shown in Fig. 12. The values of the background asymmetries averaged over all $(p_T, |\eta|)$ bins are:

\begin{align}
    a_K &= +0.0510 \pm 0.0010, \\
    a_\pi &= -0.0006 \pm 0.0008, \\
    a_p &= -0.0143 \pm 0.0342, \\
    \delta &= -0.0013 \pm 0.0002.
\end{align}

VII. MEASUREMENT OF ASYMMETRIES $a_{CP}$ AND $A_{CP}$

Using the full 10.4 fb$^{-1}$ of integrated luminosity collected by the D0 experiment in Run II we select $2.17 \times 10^9$ inclusive muon events and $6.24 \times 10^6$ like-sign dimuon events. For comparison, the number of opposite-sign dimuon events with the same selections is $2.18 \times 10^7$. The fraction of like-sign dimuon events in the present analysis common with the events used in Ref. [3] is 74%. This value reflects the changes of the sample size due to the luminosity increased from 9 fb$^{-1}$ to 10 fb$^{-1}$, and due to the additional requirement of the number of SMT hits associated with a muon, see section III for details.

The raw asymmetries $a'$ and $A'$ in a given $(p_T, |\eta|)$ bin $i$ are determined using Eqs. (3) and (21), respectively. The raw asymmetries $a$ and $A$ are obtained using Eqs. (10) and (25), respectively. The background asymmetries $a_{bkg}$ and $A_{bkg}$ are obtained using the methods presented in Sections V and VI. They are subtracted from the raw asymmetries $a$ and $A$ to obtain the residual asymmetries $a_{CP}$ and $A_{CP}$.

The raw asymmetry $a$, the contribution of different background sources, and the residual asymmetry $a_{CP}$, for the total inclusive muon sample and for different IP samples are given in Table VIII. This table gives the values with statistical uncertainties only. The asymmetry $a_{CP}$ with both statistical and systematic uncertainties is given in Table IX.

The charge asymmetry of $S$ muons in the inclusive muon sample is expected to be small, see Section VIII for details. Thus, the observed inclusive single muon asymmetry is expected to be consistent with the estimated background within its uncertainties. Therefore, the comparison of the observed and expected inclusive single muon asymmetries provides a stringent closure test and validates the method of background calculation. In the present analysis such a comparison is performed both
TABLE VIII: Contributions to background asymmetry $a_{\text{bkg}}$, the raw asymmetry $a$, and the residual charge asymmetry $a_{\text{CP}}$ in the IP samples of the inclusive muon sample. FIG. 13: (a) The asymmetry $a_{\text{bkg}}$ (points with error bars representing the statistical uncertainties), shown in each $(p_T, |\eta|)$ bin $i$, is compared to the measured asymmetry $a$ for the total inclusive muon sample (shown as a histogram, since the statistical uncertainties are negligible). The asymmetry from CP violation is negligible compared to the background uncertainty in the inclusive muon sample. The vertical dashed lines separate the $(p_T, |\eta|)$ bins corresponding to the central, intermediate, and forward regions of the D0 detector, respectively. (b) The asymmetry $a_{\text{CP}}$. The horizontal dashed line shows the value of $a_{\text{CP}}$ defined as the weighted sum in Eq. (11).

FIG. 14: Same as Fig. 13 for IP=1 sample.

The comparison shows an excellent agreement between the observed and expected asymmetries in different kinematic $(p_T, |\eta|)$ bins and in different IP samples. The difference for the total sample is consistent with zero within 0.042% accuracy, while the raw asymmetry varies as much as 1.5% between $(p_T, |\eta|)$ bins. This result agrees with the expectation that the charge asymmetry of $S$ muons in the inclusive muon sample should be negligible compared to the uncertainty of the background asymmetry, see Tables VIII and XV.

The comparison of observed and expected asymmetries in the three non-overlapping IP samples does not reveal any bias with the change of the muon IP. The values of $\chi^2(a_{\text{CP}})$ in Table IX are obtained with statistical uncertainties only. The compatibility of these values with the statistical $\chi^2$ distribution indicates that the systematic uncertainties do not depend on the kinematic properties of the event. For the IP=3 sample the contribution of the background asymmetry is strongly suppressed. Therefore, the observed asymmetry is sensitive to a possible charge asymmetry of $S$ muons, which could be reflected for the total inclusive muon sample and for the IP samples. The results are shown in Figs. 13-16. The $\chi^2(a_{\text{CP}})$ of the fits of the differences $a - a_{\text{bkg}}$ to their averages are given in Table IX. For each fit the number of degrees of freedom is equal to eight. Only the statistical uncertainties of $a$ and $a_{\text{bkg}}$ are used to compute $\chi^2(a_{\text{CP}})$.
the three non-overlapping IP samples, including the systematics uncertainties, is less than two standard deviations. The obtained deviation, taking into account the systematic uncertainty, is approximately the same magnitude, see Table VIII. In both cases the expected asymmetry follows the variation of the observed asymmetry in different kinematic bins, so that the prediction and the observation agree within statistical uncertainties. Thus, the closure test provides the confidence in the measurement of the like-sign dimuon charge asymmetry, where the same method of background measurement is applied.

The dimuon raw asymmetry $A$, the contribution of different background sources, and the residual asymmetry $A_{\text{CP}}$ for the total like-sign dimuon sample and for different (IP1, IP2) samples are given in Table X.

The comparison of the observed and expected background asymmetries in different kinematic bins is shown in Fig. 17. The asymmetry $A^i$ in each $(p_T, |\eta|)$ bin is defined in Eq. (21). The expected background asymmetry $A^i_{\text{bkg}}$ is computed using Eq. (23). There are two entries per like-sign dimuon event corresponding to the $(p_T, |\eta|)$ values of each muon. Figures 18 and 19 show the values of $A^i_{\text{CP}}$ in each $(p_T, |\eta|)$ bin for different IP1, IP2 samples. The last bin separated by the vertical line shows the value of $A_{\text{CP}}$ defined as the weighted sum in Eq. (26) and its statistical uncertainty.

The quality of agreement between the observed and expected background asymmetries in different kinematic bins $(p_T, |\eta|)$ is given by $\chi^2(A_{\text{CP}})$, which is obtained from the fit of the differences $A^i - A^i_{\text{bkg}}$ to their average. The values of $\chi^2(A_{\text{CP}})$ are given in Table XI. The correlation of the $A^i$ and $A^i_{\text{bkg}}$ between different $(p_T, |\eta|)$ bins is taken into account in these $\chi^2(A_{\text{CP}})$ values. For each sample the number of degrees of freedom is equal to eight. Only the statistical uncertainties of $A^i$ and $A^i_{\text{bkg}}$ are used to compute $\chi^2(A_{\text{CP}})$.

The comparison shown in Fig. 17 demonstrates that the expected background asymmetry $A^i_{\text{bkg}}$ follows the changes of the observed asymmetry $A^i$ in different kinematic bins $(p_T, |\eta|)$ within their statistical uncertainties. However, the overall deviation of $A - A_{\text{bkg}}$ from zero ex-

### Table IX: Residual asymmetry $a_{\text{CP}}$ in the full inclusive muon sample (row “All IP”), and in different IP samples. The first uncertainty is statistical and the second uncertainty is systematic. The last column gives the $\chi^2$ of the fit of the asymmetries $a_{\text{CP}}$ in nine $(p_T, |\eta|)$ bins $i$ to their average.

in the deviation of $a_{\text{CP}}$ from zero for this sample. Still, this deviation, taking into account the systematic uncertainty, is less than two standard deviations. The obtained values of $a_{\text{CP}}$ in the total inclusive muon sample and in the three non-overlapping IP samples, including the systematic uncertainties, are given in Table IX.

The last bin separated by the vertical line shows the value of $A_{\text{CP}}$ defined as the weighted sum in Eq. (26) and its statistical uncertainty. The horizontal dashed line corresponds to this value of $A_{\text{CP}}$.

ceeds three times the statistical uncertainty for the total like-sign dimuon sample, and is present with less significance in each (IP$_1$,IP$_2$) sample.

The obtained values of $A_{\text{CP}}$ are given in Table XI. The correlation matrix of the measured asymmetries $a_{\text{CP}}$ and $A_{\text{CP}}$ is given in Table XII. The large correlation between
some measurements is because of the common statistical and systematic uncertainties of the background, see Appendix A for details. The asymmetries $a_{CP}$ and $A_{CP}$ measured with full inclusive muon and like-sign dimuon samples without dividing them into IP samples are given in rows “All IP” of Tables IX and XI. The correlation between these measurements is

$$\rho = 0.782. \quad (54)$$

Figure 20 presents the asymmetries $a_{CP}$ and $A_{CP}$.

The obtained values $a_{CP}$ and $A_{CP}$ for all events in Tables IX and XI can be compared with our previous results [3] obtained with 9.1 fb$^{-1}$ of integrated luminosity presented in Tables XIII and XIV. The previous and new results are consistent and the difference between them is small as the weighted sum in Eq. (26) and its statistical uncertainty. The last column gives the $\chi^2$ of the fit of the asymmetries $A_{CP}$ in nine $(p_T, |\eta|)$ bins to their average.

them is attributed to a more detailed measurement of the background asymmetry using $(p_T, |\eta|)$ bins in the present analysis. During data taking in Run II we published several measurements of $a_{\text{CP}}$ and $A_{\text{CP}}$ [28]. The value of $a_{\text{CP}}$ is changed between Ref. [2] and [3] because of the change in the method of background measurement. This change does not exceed the assigned systematic uncertainty. Otherwise, the results demonstrate a good stability despite the increase by an order of magnitude in the integrated luminosity, and the many improvements of the analysis methods over the years.

The values given in Tables IX, XI and XII constitute the main model-independent results of this analysis.

VIII. SOURCES OF CHARGE ASYMMETRY

This analysis is performed at a $p\bar{p}$ collider. Due to CP-invariant initial state, we assume no production asymmetry of muons. In the following, we consider the contributions to the charge asymmetries $a_{\text{CP}}$ and $A_{\text{CP}}$ coming from CP violation in both mixing of neutral $B$ mesons and in interference of $B$ decays with and without mixing. Because our measurements are inclusive, other as yet unknown sources of CP violation could contribute to the asymmetries $a_{\text{CP}}$ and $A_{\text{CP}}$ as well. These sources are not discussed in this paper.

Assuming that the only source of the inclusive single muon charge asymmetry is CP violation in $B^0$-$\bar{B}^0$ and $B^0_d$-$\bar{B}^0_d$ mixing, the asymmetry $a_S$ defined in Eq. (11) can be expressed as

$$a_S = c_b A^b_{sl}. \quad (55)$$

The coefficient $c_b$, obtained from simulation, represents the fraction of muons produced in the semileptonic decay of $B$ mesons that have oscillated among all $S$ mesons. This fraction is typically 3% – 11% depending on IP as shown in Table XV. The semileptonic charge asymmetry $A^b_{sl}$ has contributions from the semileptonic charge asymmetries $a^d_{sl}$ and $a^s_{sl}$ of $B^0$ and $B^0_s$ mesons [6], respectively:

$$A^b_{sl} = C_d a^d_{sl} + C_s a^s_{sl}. \quad (56)$$

The charge asymmetry $a^q_{sl}$ ($q = d, s$) of “wrong-charge” semileptonic $B^0_q$ meson decay induced by oscillations is defined as

$$a^q_{sl} = \frac{\Gamma(B^0_q(t) \to \mu^+ X) - \Gamma(\bar{B}^0_q(t) \to \mu^- X)}{\Gamma(B^0_q(t) \to \mu^+ X) + \Gamma(\bar{B}^0_q(t) \to \mu^- X)}. \quad (57)$$

This quantity is independent of the proper decay time $t$ [32].

The semileptonic charge asymmetry $a^q_{sl}$ ($q = d, s$) depends on the complex non-diagonal parameters of the mass mixing matrix $M_q + i\Gamma_q$ of the neutral ($B^0_{d,L}, B^0_{d,H}$) meson system [8] as

$$a^q_{sl} = \frac{\Delta \Gamma_q}{\Delta m_q} \tan(\phi^q_{12}), \quad (58)$$

$$\Delta m_q \equiv m_q^H - m_q^L = 2|m_q^{12}|, \quad (59)$$

$$\Delta \Gamma_q \equiv \Gamma^L_q - \Gamma^H_q = 2|\Gamma_q^{12}| \cos(\phi^q_{12}), \quad (60)$$

$$\phi^q_{12} \equiv \arctan \left( \frac{-m_q^{12}}{\Gamma_q^{12}} \right). \quad (61)$$
Here \( m_{q}^{L,H} \) and \( \Gamma_{q}^{L,H} \) are the mass and width of the light (\( L \)) and heavy (\( H \)) member of the \( B_{q}^{0} \) system, respectively. \( \phi_{q}^{12} \) is the CP-violating phase of the \( (B_{q}^{0,L}, B_{q}^{0,H}) \) mass matrix. With this sign convention, both \( \Delta m_{q} \) and \( \Delta \Gamma_{q} \) are positive in the SM.

The asymmetries \( a_{d}^{4} \) and \( a_{s}^{4} \) within the SM are predicted [9] to be significantly smaller than the background asymmetries and current experimental precision:

\[
a_{d}^{4} = (-4.1 \pm 0.6) \times 10^{-4}, \quad a_{s}^{4} = (1.9 \pm 0.3) \times 10^{-5}. \tag{62}
\]

Measurements of \( a_{d}^{4} \) and \( a_{s}^{4} \) [11, 29–31] agree well with the SM expectation.

The coefficients \( C_{d} \) and \( C_{s} \) depend on the mean mixing probabilities \( \chi_{d} \) and \( \chi_{s} \) and on the production fractions \( f_{d} \) and \( f_{s} \) of \( B_{d}^{0} \) and \( B_{s}^{0} \) mesons, respectively. The mixing probability of a neutral \( B_{d}^{0} \) meson is proportional to \( 1 - \cos(\Delta m_{d} t) \), where \( t \) is the proper decay time [32] of the \( B_{d}^{0} \) meson. The mean proper decay time of \( B_{d}^{0} \) mesons is increased in the samples with large IP. Because the value of \( \Delta m_{d} \) is comparable to the width \( \Gamma_{d} \), selecting muons with large IP results in an increase of the mean mixing probability \( \chi_{d} \). The values of \( \chi_{d} \) in different IP samples are obtained using simulation and are given in Tables XV and XVI. On the contrary, the mass difference \( \Delta m_{s} \) of the \( B_{s}^{0} \) meson is very large compared to its width \( \Gamma_{s} \), and the different IP samples have approximately the same value of \( \chi_{s} \approx 0.5 \). The coefficients \( C_{d} \) and \( C_{s} \) in a given sample are computed using the following expressions:

\[
C_{d} = f_{d} \chi_{d}/(f_{d} \chi_{d} + f_{s} \chi_{s}), \tag{63}
\]

\[
C_{s} = 1 - C_{d}. \tag{64}
\]

Thus, the contribution of the asymmetries \( a_{d}^{4} \) and \( a_{s}^{4} \) to the asymmetry \( A_{b}^{4} \) is different for different IP samples, with \( C_{d} \) increasing in the range \( 31\% - 73\% \) when moving from smaller to larger IP (see Tables XV and XVI). We use the values of \( f_{d} \) and \( f_{s} \) measured at Tevatron as averaged by the Heavy Flavor Averaging Group (HFAG) [11]:

\[
f_{d} = 0.401 \pm 0.007, \tag{65}
\]

\[
f_{s} = 0.107 \pm 0.005. \tag{66}
\]

The two largest SM contributions to the like-sign dimuon charge asymmetry are CP violation in \( B_{d}^{0}, B_{s}^{0} \) and \( B_{d}^{0}, B_{s}^{0} \) mixing, \( A_{S}^{\text{mix}} \) [8], and CP violation in interference of \( B_{d}^{0} \) and \( B_{s}^{0} \) decay amplitudes with and without mixing, \( A_{S}^{\text{int}} \) [7]. Thus, the asymmetry \( A_{S} \) defined in Eq. (26) is expressed as

\[
A_{S} = A_{S}^{\text{mix}} + A_{S}^{\text{int}}, \tag{67}
\]

\[
A_{S}^{\text{mix}} = C_{s} A_{b_{s}}^{0}, \tag{68}
\]

The first contribution, \( A_{S}^{\text{mix}} \), due to CP violation in mixing, is proportional to \( A_{b_{s}}^{0} \), with the coefficient \( C_{s} \) typically 45\% - 58\% (see Table XVI). The second contribution, \( A_{S}^{\text{int}} \), is generated by the CP violation in the decay \( B_{d}^{0}(\bar{B}_{d}^{0}) \rightarrow c\bar{c}d\bar{d} \). This final state is accessible for both \( B^{0} \) and \( \bar{B}^{0} \), and the interference of decay amplitudes to these final states with and without \( B^{0}\bar{B}^{0} \) mixing results in CP violation. This contribution was not included before in the SM estimate of the dimuon charge asymmetry. It can be shown [7] that this CP violation in interference produces a like-sign dimuon charge asymmetry, while it does not contribute to the inclusive single muon charge asymmetry. An example of the final state produced in \( B^{0}(\bar{B}^{0}) \rightarrow c\bar{c}d\bar{d} \) decay is \( B^{0}(\bar{B}^{0}) \rightarrow D^{(*)+}D^{(*)-} \). Similar contribution of CP violation in \( B_{s}^{0} \rightarrow c\bar{c}s\bar{s} \) decay is found to be negligible [7] and is not considered in our analysis.

The value of \( A_{S}^{\text{int}} \) is obtained using the following expression [7]:

\[
A_{S}^{\text{int}} = -0.5 f_{d} R_{d} R_{P} \Delta \Gamma_{d} \sin(2\beta) I, \tag{69}
\]

where

\[
R_{d} = \frac{B(c\bar{c}d\bar{d} \rightarrow \mu X)}{B(c\bar{c}X \rightarrow \mu X)}, \tag{70}
\]

\[
R_{P} = \frac{P(b \rightarrow c\bar{c}X \rightarrow \mu X)(P(b) - P(\bar{b}))}{P(b)P(\bar{b})}, \tag{71}
\]

\[
I = \Gamma_{d} \int \exp(-\Gamma_{d} t) \sin(\Delta m_{d} t) dt. \tag{72}
\]

Here the ratio \( R_{d} \) reflects the fact that the final state of the decay \( B^{0} \rightarrow c\bar{c}d\bar{d} \) contains more \( D^{\pm} \) mesons than the generic \( b \rightarrow c\bar{c}X \) final state, and that the branching fraction of \( D^{\pm} \rightarrow \mu^{\pm}X \) decays is much larger than that of all other charmed hadrons. Using the known branching fractions of \( b \) - and \( c \)-hadron decays taken from Ref. [5], we estimate

\[
R_{d} = 1.5 \pm 0.2. \tag{73}
\]

In the expression for \( R_{P} \), the quantity \( P(b \rightarrow c\bar{c}X \rightarrow \mu X) \) is the probability to reconstruct a muon coming from the decay \( b \rightarrow c\bar{c}X \rightarrow \mu X \). It depends on the muon reconstruction efficiency, including all fiducial requirements, and on the branching fractions of the decays \( b \rightarrow c\bar{c}X \) and \( c \rightarrow \mu X \). The quantity \( P(b) \) is the probability to reconstruct a “right-sign” muon from the \( b \rightarrow \mu^{-} \) decay. It includes both the muon reconstruction efficiency and the branching fractions of all possible decay modes of \( b \) quarks producing a “right-sign” muon. Similarly, the quantity \( P(\bar{b}) \) is the probability to reconstruct a “wrong-sign” muon from the \( b \rightarrow \mu^{-} \) decay. All these probabilities depend on the IP requirement. They are determined using simulation. The values of \( R_{P} \) for different IP samples are given in Table XVI.

The branching fraction \( B(b \rightarrow c\bar{c}X) \) of \( b \)-hadron decays producing a \( c\bar{c} \) pair is obtained using the experimental value of \( B(b\text{-hadron mixture} \rightarrow c/\bar{c}X) \) measured at LEP [5]:

\[
B(B \text{ mixture} \rightarrow c/\bar{c}X) = (116.2 \pm 3.2)\%, \tag{74}
\]

where \( “c/\bar{c}” \) counts multiple charm quarks per decay. Assuming a negligible fraction of charmless \( b \)-hadron decays, we derive from Eq. (74) the following value for the
branching fraction of decay of $b$ quark into two charm quarks:

$$B(b \rightarrow c\bar{c}X) = (16.2 \pm 3.2)\%.$$  \hfill (75)

The angle $\beta$ is one of the angles of the unitarity triangle defined as

$$\beta = \arg \left( \frac{V_{cd}V_{cb}^*}{V_{td}V_{tb}^*} \right),$$  \hfill (76)

where the quantities $V_{cq'}$ are the parameters of the CKM matrix. The world average value of $\sin(2\beta)$ [5] is

$$\sin(2\beta) = 0.679 \pm 0.020.$$  \hfill (77)

The SM prediction [9]

$$\frac{\Delta\Gamma_d}{\Gamma_d} (\text{SM}) = (0.42 \pm 0.08) \times 10^{-2},$$  \hfill (78)

is used in our estimate of the SM expectation of the $A_{\text{CP}}^{\text{int}}$ asymmetry. The precision of the measured world average of $\Delta\Gamma_d/\Gamma_d$ [5] is about 20 times larger:

$$\frac{\Delta\Gamma_d}{\Gamma_d} = (1.5 \pm 1.8) \times 10^{-2}.$$  \hfill (79)

Finally, the integration in Eq. (72) is taken over all $B^0$ decays in a given IP sample. For the total dimuon sample it can be obtained analytically with the result

$$I = \frac{x_d}{1 + x_d^2},$$  \hfill (80)

$$x_d = \frac{\Delta m_d}{\Gamma_d}.$$  \hfill (81)

For the IP samples the value of $I$ is obtained in simulation with simulation and the results are given in Table XVI. The CP violation in interference of $B^0_\text{d}$ decay amplitudes with and without mixing is expected to be significantly smaller than the contribution from $B^0_\text{s}$ mesons [7] due to the relatively small values of $x_s/(1 + x_s^2)$ and $\sin(2\beta_s)$. The contribution due to $B^0_\text{s}$ mesons is neglected in this analysis.

Hence, to determine the expected SM values of asymmetries $a_S$ and $A_S$ we need the following quantities, all extracted from simulation, and all listed in Tables XV and XVI:

- The fractions $c_b$ and $C_b$, in different IP samples.
- The coefficient $C_d$, itself derived from the average mixing probability $\chi_d$, in different IP samples.
- The quantities $R_P$ and $I$, required to evaluate the contribution $A_{\text{CP}}^{\text{int}}$, in different IP samples.

The coefficients $C_b$ and $R_P$ are determined using the simulation of $b\bar{b}$ and $c\bar{c}$ events producing two muons. This simulation allows an estimate of these coefficients taking into account the possible correlation in the detection of two muons. This simulation was not available for our previous measurement [3]. For comparison, the value of $C_b$ used in Ref. [3] for the full sample of dimuon events was $C_b = 0.474 \pm 0.032$. The uncertainty on all quantities listed in Tables XV and XVI include the uncertainty on the input quantities taken from Ref. [5] and the limited simulation statistics. In addition, the uncertainty on the
coefficients \( c_0 \), \( C_0 \), and \( R_P \) includes the uncertainty on the momentum of the generated \( b \) hadrons.

In addition, in order to convert the asymmetries \( a_S \) and \( A_S \) into the asymmetries \( a_{\text{CP}} \) and \( A_{\text{CP}} \) using Eqs. (11) and (26), the fractions \( f_S \), \( F_{SS} \) and \( F_{SL} \) are required. These quantities are obtained using the values \( f_K \), \( f_\pi \), \( f_\mu \), \( F_K \), \( F_\pi \), and \( F_\mu \). All of them are measured in data and given in Tables V and VI. We also need the following quantities extracted from simulation and listed in Tables XV and XVI:

- The quantities \( C_K \), and \( C_\pi \) in different IP samples. They are defined in Eq. (8).
- The quantity \( R_{LL} \) in different IP samples. It is defined in Eq. (34).

The coefficients \( C_K \) and \( C_\pi \) are defined as the fraction of \( K \rightarrow \mu \) and \( \pi \rightarrow \mu \) tracks with the reconstructed track parameters corresponding to the track parameters of the kaon or pion, respectively. Since the kaons and pions are mainly produced in the primary interactions, such muons have small IP. If, on the contrary, the reconstructed muon track parameters correspond to the track parameters of the muon from \( K^\pm \rightarrow \mu^\pm \nu \) and \( \pi^\pm \rightarrow \mu^\pm \nu \) decay, the IP of such muons is large because the kaons and pions decay at a distance from the primary interaction and the muon track has a kink with respect to the hadron’s trajectory. Therefore, the fraction of such muons increases with increasing IP, and the coefficients \( C_K \) and \( C_\pi \) become small for the samples with large IP.

Tables XV and XVI also include the SM expectation for \( a_S \), \( A_S^{\text{mix}} \), \( A_S^{\text{int}} \), \( a_{\text{CP}} \), and \( A_{\text{CP}} \). The expected value of \( a_S \) is smaller than that of \( A_S^{\text{mix}} \). The contribution \( A_S^{\text{int}} \) due to CP violation in interference of decay amplitudes with and without mixing exceeds that from \( A_S^{\text{mix}} \).

IX. INTERPRETATION OF RESULTS

We measure the asymmetry \( a_{\text{CP}} = a' - a_{\text{bkg}} \) in 27 bins with different \((p_T, |\eta|)\) and IP, and the asymmetry \( A_{\text{CP}} = A' - A_{\text{bkg}} \) in 54 bins with different \((p_T, |\eta|)\), IP1, and IP2, and compare the result with the SM prediction.

The largest SM contributions to the inclusive single muon and like-sign dimuon charge asymmetries come from CP violation in \( B^0 \)-\( \bar{B}^0 \) and \( B_L^0 \)-\( B_R^0 \) mixing, and CP violation in interference of \( B^0 \) and \( B^0 \) decay amplitudes with and without mixing. The expected numerical values of these contributions to the asymmetries \( a_S \) and \( A_S \) are given in Tables XV and XVI. The asymmetries \( a_S \) and \( A_S \) are related to the residual asymmetries \( a_{\text{CP}} \) and \( A_{\text{CP}} \) as

\[
a_{\text{CP}} = f_S a_S, \tag{82}
a_{\text{CP}} = F_{SS} A_S + F_{SL} a_S, \tag{83}
\]

see Eqs. (11) and (26). The fractions \( f_S \), \( F_{SS} \), \( F_{SL} \) are given in Tables V and VI.

Using all these values we determine the consistency of our measurements with the SM expectation. The SM expectation for \( a_{\text{CP}} \) and \( A_{\text{CP}} \) are given in Tables XV and XVI, respectively. The expectation for \( a_{\text{CP}}(\text{SM}) \) is significantly smaller in magnitude than the experimental uncertainty for all IP samples. The measured \( A_{\text{CP}} \) are systematically larger in amplitude than their corresponding \( A_{\text{CP}}(\text{SM}) \) expectations.

Using the measurements with full samples of inclusive muon and like-sign dimuon events given in rows “All IP” in Tables IX and XI and taking into account the correlation between them given in Eq. (54), we obtain the \( \chi^2 \) of the difference between these measurements and their SM expectations

\[
\chi^2/\text{d.o.f.} = 9.9/2, \quad (84)
p(\text{SM}) = 7.1 \times 10^{-3}. \quad (85)
\]

This result, that uses no IP information, corresponds to 2.7 standard deviations from the SM expectation.

The values of \( \chi^2 \) in Eq. (84), and throughout this section, include both statistical and systematic uncertainties. These \( \chi^2 \) values are minimized by a fit that takes into account all correlations between the uncertainties, see Appendix A. The \( p \) value quoted in Eq. (85), and throughout this section, is the probability that the \( \chi^2 \) for a given number of degrees of freedom (d.o.f.) exceeds the observed \( \chi^2 \). These \( p \) values are translated to the equivalent number of standard deviations for a single variable.

Using the same measurements \( a_{\text{CP}} \) and \( A_{\text{CP}} \) obtained with full inclusive muon and like-sign dimuon samples we obtain the value of the charge asymmetry \( A_{\text{sl}}^b \) defined in Eq. (56). Assuming that the contribution of CP violation in interference corresponds to the SM expectation given in Table XVI, we get

\[
A_{\text{sl}}^b = (-0.496 \pm 0.153 \pm 0.072) \times 10^{-2}. \quad (86)
\]

This value differs from the SM expectation \( A_{\text{sl}}^b = (-0.023 \pm 0.004) \times 10^{-2} \) obtained from Eq. (56) by 2.8 standard deviations.

The change in the central value and the uncertainty compared to our previous result [3] is due to several factors. The contribution of the CP violation in interference was not considered in Ref. [3]. The simulation of \( b \bar{b} \) and \( c \bar{c} \) events producing two muons, which was not available for our previous measurement, allows a better estimate of the coefficient \( C_b \). Finally, a more accurate procedure for measuring background asymmetries using \((p_T, |\eta|)\) bins results in the change of \( A_{\text{CP}} \) with respect to the previous result [3], which is also reflected in the change of the \( A_{\text{sl}}^b \) asymmetry, see Table XIV.

The comparison of our result with the SM prediction benefits from the use of each IP region separately, due to the large variations in the background fraction in each IP sample. The three measurements of \( a_{\text{CP}} \) in different IP samples and six measurements of \( A_{\text{CP}} \) in different \((\text{IP}_1, \text{IP}_2)\) samples can be compared with the SM expectation. Both statistical and systematic uncertainties are
used in this comparison. The correlation between different measurements given in Table XII are taken into account. The \(\chi^2\) (IP) of the difference between the measured residual asymmetries and the SM expectation is

\[
\chi^2\text{(IP)/d.o.f.} = 31.0/9, \quad p(\text{SM}) = 3 \times 10^{-4}.
\]

This result corresponds to 3.6 standard deviations from the SM expectation. The \(p\) value of the hypothesis that the \(a_{\text{CP}}\) and \(A_{\text{CP}}\) asymmetries in all IP samples are equal to zero is

\[
p(\text{CPV} = 0) = 3 \times 10^{-5},
\]

which corresponds to 4.1 standard deviations.

If we assume that the observed asymmetries \(a_{\text{CP}}\) and \(A_{\text{CP}}\) are due to the CP violation in mixing, the results in different IP samples can be used to measure the semileptonic charge asymmetries \(a_{\text{sl}}^d\) and \(a_{\text{sl}}^s\). Their contribution to the asymmetries \(a_{\text{CP}}\) and \(A_{\text{CP}}\), determined by the coefficients \(C_d\) and \(C_s\), varies considerably in different IP samples. Performing this measurement we assume that the contribution of the CP violation in interference of decay amplitudes with and without mixing, given by Eq. (69), corresponds to the SM expectation presented in Table XVI. In particular, the value of \(\Delta \Gamma_d/\Gamma_d\) is set to its SM expectation given in Eq. (78). We obtain

\[
a_{\text{sl}}^d = (-0.62 \pm 0.42) \times 10^{-2}, \quad a_{\text{sl}}^s = (-0.86 \pm 0.74) \times 10^{-2},
\]

\[
\chi^2/\text{d.o.f.} = 10.1/7.
\]

The correlation between the fitted parameters \(a_{\text{sl}}^d\) and \(a_{\text{sl}}^s\) is

\[
\rho_{d,s} = -0.79.
\]

The difference between these \(a_{\text{sl}}^d\) and \(a_{\text{sl}}^s\) values and the combined SM expectation (62) corresponds to 3.4 standard deviations.

The like-sign dimuon charge asymmetry depends on the value of \(\Delta \Gamma_d/\Gamma_d\), see Eqs. (56,58,67–69). By fixing the values of \(\phi_1^2\) and \(a_{\text{sl}}^d\) to their SM expectations \(\phi_1^2 = -0.075 \pm 0.024\) and \(a_{\text{sl}}^d = (+1.9 \pm 0.3) \times 10^{-5}\) [9], we can extract the value of \(\Delta \Gamma_d/\Gamma_d\) from our measurements of \(a_{\text{CP}}\) and \(A_{\text{CP}}\) in different IP samples. We obtain

\[
\Delta \Gamma_d/\Gamma_d = (+2.63 \pm 0.66) \times 10^{-2},
\]

\[
\chi^2/\text{d.o.f.} = 13.8/8.
\]

This result differs from the SM expectation (78) by 3.3 standard deviations. The values of \(\phi_1^2\) and \(\Delta \Gamma_d/\Gamma_d\) determine the value of \(a_{\text{sl}}^d\), see Eq. (58).

Finally, we can interpret our results as the measurement of \(a_{\text{sl}}^d\), \(a_{\text{sl}}^s\) and \(\Delta \Gamma_d/\Gamma_d\), allowing all these quantities to vary in the fit. We obtain

\[
a_{\text{sl}}^d = (-0.62 \pm 0.43) \times 10^{-2},
\]

\[
a_{\text{sl}}^s = (-0.82 \pm 0.99) \times 10^{-2},
\]

\[
\Delta \Gamma_d/\Gamma_d = (+0.50 \pm 1.38) \times 10^{-2},
\]

\[
\chi^2/\text{d.o.f.} = 10.1/6.
\]

The correlations between the fitted parameters are

\[
\rho_{d,s} = -0.61, \quad \rho_{d,\Delta \Gamma} = -0.03, \quad \rho_{s,\Delta \Gamma} = +0.66.
\]

This result differs from the combined SM expectation for \(a_{\text{sl}}^d\), \(a_{\text{sl}}^s\), and \(\Delta \Gamma_d/\Gamma_d\) by 3.0 standard deviations.

Figure 21 shows the 68% and 95% confidence level contours in the \(a_{\text{sl}}^d - a_{\text{sl}}^s\) plane obtained from the re-fit of the inclusive single muon and like-sign dimuon asymmetries with fixed value of \(\Delta \Gamma_d/\Gamma_d = 0.0042\) corresponding to the expected SM value (78) which has an uncertainty \(\pm 0.0008\). The independent measurements of \(a_{\text{sl}}^d\) [29] and \(a_{\text{sl}}^s\) [30] by the D0 collaboration are also shown. The error bands represent \(\pm 1\) standard deviation uncertainties of these measurements.
used instead of the SM prediction, the values of $a_{sl}^d$ and $a_{sl}^s$ become consistent with the SM expectation within two standard deviations. This observation demonstrates the importance for independent measurements of $\Delta\Gamma_d/\Gamma_d$ which have not been a high priority of experimentalists before [33].

The combination of the measurements of the semileptonic charge asymmetries $a_{sl}^d$ [29] and $a_{sl}^s$ [30] by the D0 collaboration with the present analysis of the inclusive single muon and like-sign dimuon charge asymmetries gives

$$a_{sl}^d = (-0.09 \pm 0.29) \times 10^{-2},$$

$$a_{sl}^s = (-1.33 \pm 0.58) \times 10^{-2},$$

$$\Delta\Gamma_d/\Gamma_d = (+0.79 \pm 1.15) \times 10^{-2},$$

$$\chi^2/d.o.f. = 4.4/2.$$ 

The correlations between the fitted parameters are

$$\rho_{d,a} = -0.34, \quad \rho_{d,\Delta\Gamma} = +0.24, \quad \rho_{a,\Delta\Gamma} = +0.55.$$ 

In this combination we treat all D0 measurements as statistically independent. This result differs from the combined SM expectation for $a_{sl}^d$, $a_{sl}^s$, and $\Delta\Gamma_d/\Gamma_d$ by 3.1 standard deviations. Currently, these are the most precise measurements of $a_{sl}^d$, $a_{sl}^s$, and $\Delta\Gamma_d/\Gamma_d$ by a single experiment.

Figure 23 shows the 68% and 95% confidence level contours in the $a_{sl}^d - a_{sl}^s$ plane representing the profile of the results given by Eq. (96)–(100) at the best fit value of $\Delta\Gamma_d/\Gamma_d = 0.0050$ corresponding to Eq. (98). The contours with filled area show the 68% and 95% confidence level contours in the $a_{sl}^d - a_{sl}^s$ plane representing the profile of the results obtained by the combination of all D0 measurements and given by Eq. (101)–(105) at the best fit value of $\Delta\Gamma_d/\Gamma_d = 0.0079$ corresponding to Eq. (103). The independent measurements of $a_{sl}^d$ [29] and $a_{sl}^s$ [30] by the D0 collaboration are also shown. The error bands represent $\pm 1$ standard deviation uncertainties of these measurements.

X. CONCLUSIONS

We have presented the final measurements of the inclusive single muon and like-sign dimuon charge asymmetries using the full data set of 10.4 fb$^{-1}$ collected by the D0 experiment in Run II of the Tevatron collider at Fermilab. The measurements of the inclusive muon sample are performed in 27 non-overlapping bins of $(p_T, |\eta|)$ and IP. The measurements of the like-sign dimuon sample
are performed in 54 non-overlapping bins of \((p_T, |\eta|)\), IP1 and IP2. The background contribution is measured using two independent methods that give consistent results. The achieved agreement between the observed asymmetry \(a\) and the expected background asymmetry \(a_{bkg}\) in the inclusive muon sample is at the level of \(3 \times 10^{-4}\), see Table VIII.

The model-independent charge asymmetries \(a_{CP}\) and \(A_{CP}\), obtained by subtracting the expected background contribution from the raw charge asymmetries, are given in Tables IX, XI and XII, respectively, and are shown in Fig. 20. These measurements provide evidence at the 4.1 standard deviations level for the deviation of the dimuon charge asymmetry from zero. The \(\chi^2\) of the difference between these measurements and the SM expectation of charge asymmetry from zero. The \(\chi^2\) is defined in Tables I and II.

If we interpret all observed asymmetries in terms of anomalous CP violation in neutral \(B\) meson mixing and interference, we obtain the semileptonic charge asymmetry and CP asymmetry of the \(B^0\) system: \(\Delta \Gamma_d\):

\[
a^d_{sl} = (-0.62 \pm 0.43) \times 10^{-2},
\]

\[
a^d_{sl} = (-0.82 \pm 0.99) \times 10^{-2},
\]

\[
\Delta \Gamma_d = (+0.50 \pm 1.38) \times 10^{-2},
\]

\[
\chi^2/d.o.f. = 10.1/6.
\]

The correlations between the fitted parameters are

\[
\rho_{d,s} = -0.61, \quad \rho_{d,\Delta \Gamma} = -0.03, \quad \rho_{s,\Delta \Gamma} = +0.66. \quad (110)
\]

This result differs from the SM expectation by 3.0 standard deviations.

Because our measurements are inclusive, other as yet unknown sources of CP violation could contribute to the asymmetries \(a_{CP}\) and \(A_{CP}\) as well. Therefore, the model-independent asymmetries \(a_{CP}\) and \(A_{CP}\) measured in different IP samples constitute the main result of our analysis. They are presented in a form which can be used as an input for alternative interpretations.

[4] Throughout the article, we imply the CP-conjugate reactions.
[13] Pseudorapidity is defined as \(\eta \equiv -\ln [\tan(\theta/2)]\), where \(\theta\) is the polar angle of the track relative to the proton beam direction.
[14] The impact parameter IP is defined as the distance of closest approach of the track to the \(p\bar{p}\) collision point projected onto the plane transverse to the \(p\bar{p}\) beams.
[15] The notation \(K \rightarrow \mu\) refers to charged kaons reconstructed by the central tracker and identified as muons. This group of particles includes kaon decays in flight, punch-through, or muon misidentification. The corresponding notations for charged pions and protons are \(\pi \rightarrow \mu\) and \(p \rightarrow \mu\).
[16] Samples of IP are denoted with integer numbers as defined in Tables I and II.
[18] Generally, throughout this article the word “muon” is an abbreviation for “muon candidate passing the quality requirements”.
In our previous publications [2, 3] all background fractions have been corrected by the coefficients $C_K$ and $C_s$. Therefore, the correspondence between the present (“new”) and previous (“old”) notations of the background fractions $f_S$, $f_x$, $F_K$ and $F_x$ is, e.g., $f_K$ (new) = $C_K f_K$ (old). Similarly, we do not correct the background asymmetries $a_K$ and $a_x$ by the coefficients $C_K$ and $C_s$. The correspondence between the present and previous notations of $a_K$ and $a_x$ is, e.g., $a_K$ (new) = $a_K$ (old)/$C_K$. The value of the background contributions to the charge asymmetry, e.g., $f_s a_K$, are not affected by this change of notation.

The proper decay time is the decay time of a particle in its rest frame.

In our previous publications [2, 3] all background fractions have been corrected by the coefficients $C_K$ and $C_s$. Therefore, the correspondence between the present (“new”) and previous (“old”) notations of the background fractions $f_S$, $f_x$, $F_K$ and $F_x$ is, e.g., $f_K$ (new) = $C_K f_K$ (old). Similarly, we do not correct the background asymmetries $a_K$ and $a_x$ by the coefficients $C_K$ and $C_s$. The correspondence between the present and previous notations of $a_K$ and $a_x$ is, e.g., $a_K$ (new) = $a_K$ (old)/$C_K$. The value of the background contributions to the charge asymmetry, e.g., $f_s a_K$, are not affected by this change of notation.

The systematic uncertainties of $a_K$ and $a_x$ for the measurements with $\int \text{Ld} t = 6.1$ fb$^{-1}$ and $\int \text{Ld} t = 9.0$ fb$^{-1}$ were not provided in Refs. [2] and [3]. They are provided here for the first time.

The indexes $i$ and $j$ correspond to the IP samples. The covariance matrix $V_{ij}$ is defined as

$$V_{ij} = \sum_{k=1}^{14} \sigma^i_k \sigma^j_k \rho^k_{ij}, \quad (A12)$$

$\sigma^i_k$ is the contribution to the uncertainty on $y^i$ from a given source $k$. The list of the sources of uncertainty on $y^i$ is given in Table XVIII. The parameters $\rho^k_{ij}$ are the correlation between the measurements $i$ and $j$ for the source of uncertainty $k$. The assignment of the correlation of different sources of uncertainties is set based on the analysis procedure. For example, the same muon detection asymmetry $\delta_i$ is used to measure both $a_{CP}$ and $A_{CP}$ for each IP. Therefore the correlation due to this source is set to 1. The values of $y^i$ and $\sigma^i_k$ are given in Table XIX.

Table XVIII gives the values of the correlation coefficients $\rho^k_{12}$ and $\rho^k_{14}$. For all other correlation coefficients the following relations apply:

$$\rho^k_{12} = \rho^k_{13} = \rho^k_{17} = \rho^k_{18} = \rho^k_{19} =$$

$$\rho^k_{23} = \rho^k_{24} = \rho^k_{26} = \rho^k_{29} =$$

$$\rho^k_{34} = \rho^k_{35} = \rho^k_{37} = \rho^k_{47} =$$

$$\rho^k_{48} = \rho^k_{49} = \rho^k_{59} = \rho^k_{67} =$$

$$\rho^k_{79}. \quad (A13)$$

$$\rho^k_{14} = \rho^k_{15} = \rho^k_{16} = \rho^k_{25} = \rho^k_{27} =$$

$$\rho^k_{28} = \rho^k_{36} = \rho^k_{38} = \rho^k_{39} =$$

$$\rho^k_{45} = \rho^k_{46} = \rho^k_{56} = \rho^k_{57} =$$

$$\rho^k_{58} = \rho^k_{68} = \rho^k_{69} = \rho^k_{78} =$$

$$\rho^k_{89}. \quad (A14)$$

This input is used to obtain the results given in Section IX and the correlation matrix given in Table XII.
TABLE XIX: Values of $y^i$ ($i = 1, \ldots, 9$) and the contributions to their uncertainties $\sigma^i_k$ from different sources $k$ ($k = 1, \ldots, 14$). The definition of different measurements is given in Table XVII. The definition of all sources is given in Table XVIII.
