Neutron-diffraction experiments on the (Mn,Fe)2(P, Si)-type compounds have shown a site preference of Si atoms in the trigonal prismatic (TP) site in Fe2P-type compounds. The degree of ordering of Si depends on the Si/P ratio, while it is independent of the Mn/Fe ratio. The ferromagnetic-paramagnetic magnetoelastic transition is closely related to the size of the magnetic moment on the 3f site. A preferred occupation of Si atoms on the 2c site stabilizes and decreases the magnetic moment on the 3f and 3g site, respectively, which is supported by our first-principles density functional theory calculations. This effect, together with the contribution from the Si substitution-induced changes in the interatomic distances, leads to a phase transition that is tunable in temperature and degree of first order in Mn1.25Fe0.75P1−x−Si x compounds. These results provide us with further insight into the relationship between the magnetoelastic phase transition and the local atomic coordination.

I. INTRODUCTION

The giant magnetocaloric effect (GMCE), associated with a first-order magnetoelastic transition, makes near-room-temperature magnetic refrigeration attractive as a highly efficient and environmentally benign cooling technology [1–6]. The evolution of (Mn,Fe)2(P, Si) compounds from the Fe2P parent phase by partially substituting Mn for Fe and Si for P brings tunable phase-transition temperatures and GMCE [7–9]. Neutron-diffraction experiments and first-principles calculations indicate the preferential occupation of the two transition-metal atoms in the hexagonal structure (space group P62m) [10–13]. Mn prefers the 3g site with five nonmetal nearest neighbors forming a square pyramid, while Fe favors the 3f site surrounded by four nonmetal coordination atoms forming a tetrahedron (see Fig. 1). Strong and weak magnetism appears on the 3g and 3f sites, respectively, as a consequence of the different coordination environments.

The site preference of the nonmetal substitution atoms in Fe2P can be estimated based on the atomic radii [14]. Nonmetal atoms with a larger radius than P (e.g., As and Si) are expected to occupy the 2c site, while those having a smaller radius (e.g., B) prefer the 1b site. This prediction has been experimentally confirmed in Fe2P by x-ray diffraction in the case of As substitution [15] and by Mössbauer spectroscopy for B substitution [16]. However, no experimental confirmation of the Si site preference in Fe2P(PSi)-type compounds was found.

The first-order magnetoelastic transition in Fe2P-type compounds is accompanied by changes in the density of states (DOS) of the transition-metal 3d electrons [9,17,18]. Mössbauer spectroscopy shows that Si substitution for P in Fe2P changes the local electronic structure and hyperfine fields of its coplanar Fe atoms [19]. Theoretical calculations in the (Mn,Fe)2(P, Si) yield higher Fe (Mn) moments when a larger number of coplanar Si nearest neighbors is considered [13]. The interatomic distances also significantly influence the chemical bonding between nearest neighbors, leading to changes in the transition-metal band structure and therefore magnetic moment [10,18]. In addition, magnetization measurements reveal that the ferromagnetic(FeM)-paramagnetic(FeP) phase-transition temperature (Tc) increases with increasing Si content in (Mn,Fe)2(P, Si) compounds [8]. This implies that the FeM state is stabilized by Si substitution. Consequently, it is necessary to resolve the underlying relation between the tunable phase transition and the changes in local coordination environment around transition metals in the Fe2P-type compounds upon nonmetal substitution.

In the present study, we use temperature-dependent neutron diffraction to monitor the evolution of local magnetic moments and interatomic distances across the FM-PM phase transition in (Mn,Fe)2(P, Si) compounds. Particular attention is paid to the site preference of Si atoms and its influence on local magnetic moments. Composition-specific density functional theory (DFT) calculations are performed to verify the experimental results. The influence of Si substitution on the phase transition is discussed on the basis of Si site preference and interatomic distances.

II. EXPERIMENT

The Mn1.25Fe0.75P1−x−Si x (x = 0.45, 0.50, and 0.55) compounds were prepared as described by Dung et al. [8,9]. Magnetic characterization was performed using the reciprocating sample option (RSO) mode in a superconducting quantum interference device (SQUID) magnetometer (Quantum Design MPMS 5XL). Calorimetry measurements were performed using a commercial differential scanning calorimeter (TA Instruments Q2000). In situ time-of-flight neutron powder diffraction was measured on the general materials diffractometer (GEM) at the ISIS pulsed neutron source facility.
Rutherford Appleton Laboratory, United Kingdom. The sample as coarse powder (about 7 g) was contained in an 8-mm-diameter vanadium can, which was mounted in a cryofurnace. The diffraction data were collected continuously from six banks during the heating process. The heating rate was about 1 K/min. The temperature ranges were from 10 to 260 K for the \( x = 0.45 \) sample, from 160 to 300 K for the \( x = 0.50 \) sample, and from 10 to 375 K for the \( x = 0.55 \) sample. Nuclear and magnetic structure refinement of the neutron-diffraction patterns was performed using Fullprof’s [20] implementation of the Rietveld refinement method.

In the electronic structure calculations, we used the projector augmented wave (PAW) method implemented in the Vienna Ab initio Simulation Package (VASP) [21]. Exchange interactions were taken into account using the generalized gradient approximation (GGA) by Perdew, Burke, and Ernzerhof (PBE) [22]. The Brillouin-zone integration was done using a \( \gamma \)-centered \( k \)-point mesh of \( 3 \times 3 \times 8 \) points in the irreducible part of the Brillouin zone. The cutoff energy of the augmentation function was taken as 500 eV and, for smearing, a Gaussian function was used. For all of the calculations, we relaxed the ionic positions with a force convergence of 0.001 eV/Å for all of the atoms. The energy convergence criteria was set at \( 10^{-7} \) eV.

III. RESULTS AND DISCUSSIONS

Temperature-dependent neutron-diffraction patterns are shown in Fig. 2 for the \( \text{Mn}_{1.25}\text{Fe}_{0.70}\text{P}_{1-x}\text{Si}_x \) \((x = 0.45, 0.50, \text{and } 0.55)\) compounds. All compounds display a similar evolution of the unit cell parameters with increasing temperature, i.e., a contraction in the \( ab \) plane and an expansion along the \( c \) axis. Besides, the diffraction peaks show a discontinuity at \( T_C \). This reveals the first-order nature of the magnetoelastic transition for the \( \text{Mn}_{1.25}\text{Fe}_{0.70}\text{P}_{1-x}\text{Si}_x \) compounds studied here. With increasing Si content, \( T_C \) increases, while the first-order character of the phase transition, manifest in the jump of the peak positions, decreases. This is consistent with magnetization and x-ray diffraction results previously obtained [8]. The specific heat was measured through the phase transition for the three samples. As presented in Fig. 3, the thermal hysteresis is strongly reduced from 7 to 1 K as Si content increases from 0.45 to 0.55, indicating the weakening of the first-order character of the transition. The latent heat also decreases with Si content, reflecting the decrease in the energy barrier associated with the phase transition, in agreement with the thermal hysteresis trend observed. As a result, substituting Si for P stabilizes the FM state of \( \text{(Mn,Fe)}_2\text{(P, Si)} \) compounds, while it weakens the first-order nature of the phase transition.
Figure 4 shows the neutron-diffraction pattern of the $x = 0.45$ compound in the FM state as an example. A good fit is obtained for a hexagonal structure model (space group $P6_2m$) with magnetic moments within the $ab$ plane. The detailed structure parameters and magnetic moments derived from Rietveld refinements can be seen in Table I. For these Mn-rich samples, the neutron-diffraction results reveal a clear site preference of Mn and Fe: the $3f$ sites are completely taken up by Fe and 28% by Mn. The observed site preference of Mn and Fe is in good agreement with the literature reports [10,12,13]. We further studied the distribution of Si on the $2c$ and $1b$ sites. The fraction of Si on the $2c$ site with respect to the total Si content, hereafter referred to as $f_{2c}(\text{Si})$, for the $\text{Mn}_{1.23}\text{Fe}_{0.70}\text{P}_{1-\delta}\text{Si}_{\delta}$ compounds is plotted in Fig. 5. For the present series of compounds, the $f_{2c}(\text{Si})$ increases linearly with Si content. All three compounds have a $f_{2c}(\text{Si})$ higher than expected for a random Si distribution [$f_{2c}(\text{Si}) \approx 67\%$], indicating a preferred occupation of Si on the $2c$ site rather than the $1b$ site. The Si site preference is more pronounced in the higher Si-substitution compounds. Interestingly, the $f_{2c}(\text{Si})$ in $\text{Mn}_{0.66}\text{Fe}_{0.29}\text{P}_{1-\delta}\text{Si}_{\delta}$ ($x = 0.34, 0.37,$ and 0.43) compounds [11] and in the $\text{Mn}_{1.30}\text{Fe}_{0.65}\text{P}_{0.50}\text{Si}_{0.50}$ compound [10] also present the same behavior (see Fig. 5). As a result, the Si distribution is closely related to the Si content in the compounds, while it is independent of the Mn/Fe ratio.

We also explored the Si distribution by first-principles DFT calculations. A $2 \times 2 \times 1$ supercell is built with lattice parameters $a = 6.223$ Å and $c = 3.289$ Å taken from the literature. The atomic positions: $3f$ ($x_1, 0, 0$), $3g$ ($x_2, 0, 1/2$), $2c$ ($1/3, 2/3, 0$), and $1b$ ($0, 0, 1/2$). Magnetic moments: within $ab$ plane.

</table>
The hexagonal (Mn size factor is not observed in the case of As substitution in \[ 14 \] since Si has a larger atomic radius than P. However, this lower-energy \( 2 \) reconfiguration. As a result, Si atoms prefer to occupy the electronic environment, Si induces a significant electronic contrast of the site occupation between As and P have the same number of valence electrons, while As and P likely arises from their different chemical properties. Consequently, the site preference of Si on the \( 2c \) site allows us to tune the structure is changed, allowing us to effectively tune the mixed magnetism in the system and the phase-transition character. Consequently, the site preference of Si allows us to tune the order of the phase transition, while the As atom, having the same number of valence electrons as P and thus being statistically distributed, cannot \[ 25,26 \].

FIG. 6. (Color online) The influence of Si distribution on (a) total energy and (b) sublattice magnetic moments for Mn\(_{1.25}\)Fe\(_{0.75}\)P\(_{1-x}\)Si\(_x\), from first-principles DFT calculations. The solid lines are guides to the eye.

neutron-diffraction experiments for \( x = 0.55 \). The supercell contains 15 Mn, 9 Fe, 7 Si, and 5 P atoms, with a composition Mn\(_{1.25}\)Fe\(_{0.75}\)P\(_{0.42}\)Si\(_{0.58}\) close to the \( x = 0.55 \) sample. Atomic configurations for different Si distributions on the \( 2c \) and \( 1b \) sites are modeled by filling the eight \( 2c \) sites in the supercell with a different number (3–7) of Si atoms. The corresponding \( f_{2c}(Si) \) are 3/7, 4/7, 5/7, 6/7, and 1. The total energy as a function of the \( f_{2c}(Si) \) is presented in Fig. 6(a). The total energy decreases with increasing \( f_{2c}(Si) \). This clearly reveals that Si prefers the \( 2c \) sites instead of the \( 1b \) sites, in good agreement with our experimental results and previous theoretical calculation reports \[13,23\].

The site preference of Si on the \( 2c \) site can be understood by the nonmetal atomic size factor proposed by Rundqvist \[14\] since Si has a larger atomic radius than P. However, this size factor is not observed in the case of As substitution in the hexagonal (Mn,Fe\(_2\))P\(_{1-x}\)As\(_x\) compounds. The substituted As atoms are statistically distributed on the \( 2c \) and \( 1b \) sites \[24\], although the atomic radius of As is much larger than that of P. The strong contrast of the site occupation between As and Si likely arises from their different chemical properties. As and P have the same number of valence electrons, while Si has less. Therefore, while As substitution has no effect on the electronic environment, Si induces a significant electronic reconfiguration. As a result, Si atoms prefer to occupy the lower-energy \( 2c \) site.

Figure 7 displays the thermal evolution of the sublattice magnetic moments derived from neutron-diffraction measurements for Mn\(_{1.25}\)Fe\(_{0.75}\)P\(_{1-x}\)Si\(_x\) compounds. The magnetic moment on the \( 3f \) site shows an increasing trend with increasing Si content, while the moment on the \( 3g \) site shows the opposite trend. Since the moment in the \( 3g \) site is roughly double that of the \( 3f \) site, the total moment decreases with increasing Si substitution, which is consistent with our magnetization measurements. All compounds display a similar temperature dependence of the magnetic moments on the \( 3f \) and \( 3g \) sites. The moment on the \( 3g \) site is hardly influenced by increasing temperature, whereas the moment on the \( 3f \) site drops with increasing temperature, particularly in the vicinity of \( T_C \). Besides that, our theoretical calculations \[9\] indicate that Fe on the \( 3f \) site almost loses all the magnetic moment after the ferromagnetic-paramagnetic magnetoelastic transition, while Mn on the \( 3g \) site still carries a magnetic moment of over 2 \( \mu_B \). These results demonstrate that the magnetoelastic transition in Mn\(_{1.25}\)Fe\(_{0.75}\)P\(_{1-x}\)Si\(_x\) compounds is closely linked with the decay of the magnetic moment on the \( 3f \) site. However, the high-moment state of the \( 3f \) site persists to higher temperatures for the compounds containing more Si atoms. This gives us clear evidence of the enhancement of the FM state by Si substitution for P in Mn\(_{1.25}\)Fe\(_{0.75}\)P\(_{1-x}\)Si\(_x\) compounds. Therefore, the rise in \( T_C \) of the FM-PM transition with increasing Si content (see Fig. 2) can be attributed to the stabilization of the magnetic moment on the \( 3f \) site.

The first-order phase-transition behavior in the (Mn,Fe\(_2\))(P,Si)-type compounds is closely related to the unique mixed magnetism of the system \[9,10\]. The preferred occupation of Si on the \( 2c \) site causes significant electronic reconfiguration around the \( 3f \) and \( 3g \) sites, which stabilizes and decreases the magnetic moment on the \( 3f \) and \( 3g \) site, respectively. This weakens the itinerant character of the moments on the \( 3f \) site and the localized character on the \( 3g \) site. Thus, by changing Si content, the electronic structure is changed, allowing us to effectively tune the mixed magnetism in the system and the phase-transition character.
The Fe (Mn) magnetic-moment formation is in competition with chemical bonding in the Mn\textsubscript{1.25}Fe\textsubscript{0.70}P\textsubscript{1-x}Si\textsubscript{x} compounds, which is strongly influenced by the coordination environment around the Fe (Mn) atoms. Two main contributions from the coordination atoms should be taken into consideration: the atomic species and the interatomic distances. Figure 6(b) illustrates the magnetic moments on the 3f and 3g sites as a function of f\textsubscript{2} (Si) obtained from our DFT calculations. Higher and lower magnetic moments are predicted on the 3f and 3g sites, respectively, when more Si atoms occupy the 2c sites. According to the electronic structure calculations, (Mn,Fe\textsubscript{2})\textsubscript{2}(P,Si) has only Fe and Mn d electrons close to the Fermi level, while P and Si p electrons are located far below [13]. Electron transfer from the Fe and Mn d band to the P and Si p band would be expected to fill the P and Si p band, which enhances the splitting of the Fe and Mn d band and thus increases the magnetic moment of the Fe and Mn supplying the electrons. This electron transfer feature is more pronounced for coplanar metal-nonmetal neighbors, as indicated by the isomer shift in Mössbauer spectra of Fe\textsubscript{2}(P,Si) compounds [19]. Since Si has less valence electrons than P, the preferred occupation of Si on the 2c site would bring larger magnetic moments on its coplanar 3f site. These results suggest that larger magnetic moments will develop on the 3f or 3g site when there are more coplanar Si nearest neighbors, which is in accordance with previous theoretical calculation results [13].

The interatomic distance also plays a crucial role in the competition between the magnetic moment and chemical bonding. Our neutron-diffraction experiments reveal that compared with the interlayer interatomic distances, the intralayer interatomic distances show a much stronger dependence on temperature or Si substitution. This probably arises from the reconfiguration of electronic structure during the phase transition or upon Si substitution taking place mainly within the layer. The intralayer interatomic distances decrease with rising temperature, as shown in Fig. 8. As a result, the magnetic moments decrease with increasing temperature due to the growing overlap of 3d states as well as the enhanced metal-nonmetal hybridization (see Fig. 7). Moreover, the intralayer distances expand when more Si atoms replace P (see Fig. 8). Larger magnetic moments, therefore, are expected on the 3f and 3g sites for the higher Si-containing compounds. This is confirmed by the neutron-diffraction results for the magnetic moment on the 3f site (see Fig. 7). However, the observed magnetic moment on the 3g site shows an unexpected decrease with increasing Si substitution, although the Mn(3g)-Mn(3g) distance expands. Such a deviation can be understood by the increasing Si occupancy on the 2c site with increasing Si content, as indicated in Fig. 5. In the higher Si-containing samples, less electron transfer occurs between the 3g-1b coplanar sites and it therefore causes less moment to develop on the 3g site [see Fig. 6(b)]. As a consequence, the changes in the sublattice magnetic moments induced by Si substitution are the results of both Si site preference and the varying interatomic distances.

IV. CONCLUSIONS

In summary, the local magnetic and nuclear structure in Mn\textsubscript{1.25}Fe\textsubscript{0.70}P\textsubscript{1-x}Si\textsubscript{x} (x = 0.45, 0.50, and 0.55) compounds has been monitored across the magnetoelastic transition using temperature-dependent neutron diffraction. The Si distribution on the 2c and 1b sites in the hexagonal (Mn,Fe\textsubscript{2})\textsubscript{2}(P,Si)-type compounds can be predicted based on our neutron-diffraction results, which is dependent on the Si/P ratio while independent of the Mn/Fe ratio. The FM-PM magnetoelastic transition is accompanied by the decay of the magnetic moment on the 3f site. The clear preference of Si to occupy the 2c site stabilizes and decreases the magnetic moment on the 3f and 3g site, respectively, which is supported by our first-principles calculations. The intralayer interatomic distances are expanded by Si substitution, which also enhances the magnetic moments on the 3f sites. The phase transition with tunable degree of first order and critical temperature in (Mn,Fe\textsubscript{2})\textsubscript{2}(P,Si)-type compounds is attributed to the observed Si site preference in combination with changing interatomic distances. Increasing Si content weakens the mixed magnetism in (Mn,Fe\textsubscript{2})\textsubscript{2}(P,Si)-type compounds, inducing normal ferromagnetic behavior accompanied by second-order phase transitions.
